58 ABSTRACT

59

Introduction: Liver disease is a major cause of morbidity and mortality in sub-Saharan Africa. However, its prevalence, distribution and aetiology have not been well characterised. We examined liver function tests (LFTs) and calculated liver fibrosis scores in a rural population in Uganda.

Methodology: A cross-sectional survey of LFTs was undertaken in 2011 in a rural population cohort in South-Western Uganda. We classified abnormal LFTs based on reference ranges set in America and in Africa. We derived fibrosis scores (AST to Platelet Ratio Index, fibrosis-4, GGT to platelet ratio, red cell distribution width to platelet ratio, and S-index) to evaluate the potential prevalence of liver disease. We collected information about alcohol intake, and infection with HIV, HBV and HCV, to determine the contribution made by these factors to liver inflammation or fibrosis.

59 **Results:** Data were available for 8,099 participants (median age 30 years; 56% female). The prevalence of HBV, HCV and HIV infection were 3%, 0.2% and 8%, respectively. The prevalence of abnormal LFTs 70 71 was higher based on the American reference range compared to the African reference range (e.g. for AST 12 13% vs 3%, respectively). The prevalence of AST/ALT ratio >2 was 11%, suggestive of alcoholic 13 hepatitis. The highest prevalence of fibrosis was suggested by the GPR score, with 24% of the 14 population falling above the threshold for fibrosis. By multivariate analysis, elevated LFTs and fibrosis 15 scores were most consistently associated with older age, male sex, being under-weight, infection with 76 HIV or HBV, and alcohol consumption. Based on population attributable risk, the highest proportion of 17 elevated fibrosis scores was associated with alcohol use (e.g. 64% of elevated S-index scores).

Conclusion: Further work is required to determine normal reference ranges for LFTs in this setting, to evaluate the specificity and sensitivity of fibrosis scores, and to determine aetiology of liver disease.

31 KEY FINDINGS

32 What is already known?

- Liver disease is not well characterised in many parts of sSA despite the high prevalence of chronic
 viral infections (HIV, HBV and HCV), and potential exposure to hepatotoxins including alcohol,
 aflatoxins and traditional herbal medicine.
- Non-invasive blood tests for markers of fibrosis are relatively simple and offer a safe route to 37 assess for liver fibrosis, however, their diagnostic accuracy is not well established in sSA.
- Appropriate reference ranges for LFTs are crucial for optimising the sensitivity and specificity of
 the detection of underlying liver disease.

90 What are the new findings?

- There is a disparity in the prevalence of abnormal LFTs in our study cohort when comparing two
 references ranges (American vs. local reference ranges).
- Based on GPR score, there is a high prevalence of liver fibrosis (almost 1 in 4 of this
 population) and elevated GPR score is associated with older age, male sex, being under weight, infection with HIV or HBV, and alcohol consumption.
 - Alcohol consumption accounted for 64% of abnormal S-index scores, 32% of elevated FIB-4 scores, and 19% of GPR abnormalities.

98 What do the new findings imply?

- Appropriate reference ranges for LFTs are necessary to contribute to an understanding of the
 burden and aetiology of liver disease.
- Alcohol, HIV and HBV are risk factors for deranged LFTs and liver fibrosis, with alcohol making the
 most significant and striking contribution.
 - Further investigation is needed to determine other factors that contribute to liver disease in this setting.

)7

)6 **INTRODUCTION**

)7 Liver disease causes an estimated 200,000 deaths each year in sub-Saharan Africa (sSA) as a result of)8 liver cirrhosis and hepatocellular carcinoma (1). More than 80% of Africa's burden of liver disease has)9 been attributed to endemic blood borne virus (BBV) infections, such as HIV, hepatitis B (HBV) and 10hepatitis C (HCV), alcohol, hepatotoxic medications (including traditional and herbal medicines), nonalcoholic fatty liver disease (NAFLD) and exposure to aflatoxins (1-3). However, the prevalence, 1 12distribution and aetiology of liver disease in many parts of Africa have not been well characterised, and the neglect of cirrhosis has recently been highlighted (2). In order to improve screening for liver disease, 13 4 and to implement appropriate investigations and intervention, we have undertaken a survey of liver 15 function tests (LFTs) together with demographic data for a large rural cohort in South-Western Uganda (4). 6

8 LFTs are usually the first approach to evaluation of liver disease (reference ranges and causes of 9 derangement are summarised in Suppl Table 1). In addition, liver synthetic function can be assessed by 20 measuring prothrombin time; platelet production may be decreased in chronic liver disease due to 21 hypersplenism, decreased thrombopoietin levels and bone marrow suppression (5). Abnormal LFTs are 22 often non-specific and can arise transiently in association with many acute illnesses or usage of 23 medications. However, persistent derangement can indicate chronic liver disease, with associated 24 morbidity and mortality (6). The pattern of derangement can sometimes help to establish aetiology – for 25 example AST/ALT ratio >2 is characteristically associated with alcoholic hepatitis (7.8).

26

17

27 Determination of the origin of liver disease and ascertainment of treatment requirements necessitates 28 accurate characteristation of the degree of liver disease. Liver biopsy allows objective grading of fibrosis 29 and can provide information about the likely aetiology of liver disease based on specific changes to 30 cellular architecture. However, biopsy is costly, requires experts to undertake the procedure and analyse 31 samples, and exposes patients to potentially life-threatening risks. Imaging can also be employed to 32 assess fibrosis. Typically, this comprises ultrasound-based techniques, including fibroscan to derive 33 elastography scores. In most low and middle-income settings, evaluation of liver disease currently 34 depends on use of non-invasive (blood) markers, combined with ultrasound and/or fibroscan when 35 available.

36

Non-invasive fibrosis blood tests are relatively simple and offer a safe route to assess for liver fibrosis,
 appealing in resource limited settings. Scores of liver fibrosis, such as AST to Platelet Ratio Index (APRI),
 fibrosis-4 (FIB-4), GGT to platelet ratio (GPR), red cell distribution width to platelet ratio (RPR) and S-

index have been derived using liver enzymes (ALT, AST, GGT) in combination with platelet count. However diagnostic accuracy is not well established in sSA and can be influenced by the population being assessed and the nature of underlying liver disease (9–14). GPR has recently been reported as an independent predictor of significant fibrosis in treatment naïve Gambian patients with chronic hepatitis B (CHB) infection (12). However, further studies are needed to determine the specificity and sensitivity of different scores in different settings.

16

17 Appropriate reference ranges for LFTs are crucial for optimising the detection of underlying liver disease 18 (15). Application of reference ranges defined in one setting to different populations may lead to either 19 under- or over-estimation of abnormalities (15–17). As well as being dependent on the population being 50 assessed, the distribution of LFTs in any given setting can also be influenced by the type of instrument, reagents used, and the strength of guality assurance (17). Efforts have been made to establish 51 52 'population-specific' reference ranges (16,18); one example is through the application of cross-sectional 53 data from seven South-Eastern African countries (16). However, such local reference ranges for Africa 54 have been derived from cross-sectional data collected in adults without addressing the potential 55 prevalence of underlying liver disease. Thus, while American reference ranges potentially over-estimate of the burden of liver disease in an African setting, it is also possible that locally derived reference ranges 56 57 under-estimate the burden (as they are based on thresholds that have been derived from populations in 58 which liver disease is highly prevalent).

59

56

We here set out to assess LFTs and fibrosis scores derived from a large, well defined population cohort in rural South-Western Uganda (19). We applied reference ranges set in both America and in Africa (16,20), in order to assess the possible burden of liver disease, highlighting the discrepancies that arise as a result of the difference between thresholds. We derived fibrosis scores to further evaluate the potential prevalence of liver disease in this setting and to estimate the contributions of alcohol and BBVs to the burden of disease.

57 **METHODS**

58 Study design and study population

We conducted a cross-sectional study in a rural population in Kyamulibwa, in the Kalungu district of South-Western Uganda as part of the survey of the General Population Cohort (GPC). The GPC is a community-based cohort established in 1989 with funding from the UK Medical Research Council (MRC) in collaboration with the Uganda Virus Research Institute (UVRI) (21). Regular census and medical

surveys have been conducted in this population cohort. In 2011, data collection included screening for viral hepatitis and LFTs among 8,145 adults (\geq 16 years), which we used for this analysis.

15

⁷⁶ Data collection

17 Demographic and health history data were collected using questionnaires and standardised procedures 78 described elsewhere (21,22). Blood samples were drawn at home and transported for testing at the 79 Medical Research Council central laboratories in Entebbe. LFTs (serum AST, ALT, ALP, GGT and BR) 30 were measured using a Cobas Integra 400 plus machine, with Roche reagents. Screening for HIV testing 31 was done using an algorithm recommended by the Uganda Ministry of Health, based on initial screening 32 with a rapid test. If the test result was negative, the participant was considered to be HIV negative. If the 33 test result was positive, the sample was re-tested with the rapid test HIV-1 or -2 Stat-Pak. If both tests 34 resulted in a positive result, the participant was diagnosed as HIV positive. If the tests gave discordant 35 results, the sample was further evaluated with the rapid test Uni-Gold Recombinant HIV-1/2. For those 36 samples assessed by all three tests, two positive test results were interpreted as positive, and two negative results were considered negative. HBV surface antigen (HBsAg) testing was conducted using 37 38 Cobas HBsAg II (2011-08 V10), and those who tested positive were invited for further serologic testing. HCV was tested using a combination of immunoassays followed by PCR, as previously described (23). 39)() Normal serum levels of liver enzymes were classified according to the American reference range (ARR, MGH Clinical Laboratories) and Local Reference Ranges (LRR, (16); Suppl Table 1). We excluded)1 **)**2 individuals ≤19 years from ALP analysis, since elevated ALP can be attributable to bone growth in **)**3 teenagers.

)4

Data from the full blood count was used to calculate fibrosis scores (mean corpuscular volume, MCV and platelet count). This was collected starting part-way through the 2011 data collection period; the data are, therefore, population-based, although based on only a subset of the whole cohort (n=1,877).

)8

OBJ ODE ODE

Where data were available (n=1,877), we calculated APRI, FIB-4, GPR, RPR and S-Index. The formulae for calculating these scores are presented in Suppl Table 2, along with the sensitivity and specificity of each, based on previous studies. We used previously established thresholds to suggest the presence of liver fibrosis, as follows: APRI >0.7 (24), FIB-4 >3.25 (25), GPR >0.32 (12), RPR >0.825 (26), S-index >0.3 (27). We calculated AST/ALT ratio; a score >2 has been associated with alcoholic hepatitis (8).

)5

)6 Statistical Analysis

We analysed data using standard statistical software, Stata/IC 13 (Stata Corporation, College Station, USA) and GraphPad Prism v7^{.0}. We summarised participant baseline characteristics using proportions (%) and these were stratified by sex. We reported prevalence and distribution of LFTs, laboratory markers of fibrosis and elastography scores using descriptive statistics. We reported p-values from chi-square tests, comparing the proportions of each potential risk factor between male and female participants.

12

13 We used logistic regression in our univariate and multivariate analyses, using the threshold for 4 significance set at 0.05, to estimate the odd ratios (OR), along with its 95% confidence intervals (95% CI), 15 to identify potential factors associated with abnormal LFTs and liver fibrosis scores, using a forward stepwise approach to develop our multivariate models. We added risk factors that were identified in the 6 17 age and sex adjusted univariate analysis to the multivariate model. The final multivariate models for each 8 LFT and liver fibrosis score were obtained by excluding variables in the final model until all remaining 9 variables were associated with abnormal LFTs and liver fibrosis scores at the p<0.05 threshold. Once the final multivariate model had been established, variables that were eliminated through this forward 20 stepwise approach were added back to the model and were reported if associated at the p<0.05 21 22 threshold, to reduce the effects of residual confounding. Due to the low number of individuals with active 23 HCV infection at the time of the study, we did not include this sub-group in univariate or multivariate 24 analysis. These HCV RNA positive individuals have been described in more detail elsewhere (28). We 25 present results of multivariate analysis in the form of Forrest plots generated using Microsoft Excel. A tabular form of the multivariate analysis containing the adjusted odds ratios (Adj. OR), and 95% CIs are 26 27 included in the supplementary section of the manuscript.

28

29 Ethics

Ethics approval was provided by the Science and Ethics Committee of the Uganda Virus Research Institute (GC/127/12/11/06), the Ugandan National Council for Science and Technology (HS870), and the East of England-Cambridge South (formerly Cambridgeshire 4) NHS Research Ethics Committee UK (11/H0305/5). All participants provided written informed consent.

34

35 **RESULTS**

Characteristics of study population

We analysed complete data for 8,099 participants (Suppl Table 3). Compared to females, there were more males who were HBV positive, (prevalence 3% vs 2%, respectively; p<0.001) and had consumed alcohol in the past 30 days, (40% vs 33%, respectively; p<0.001). More females were HIV positive (9%

vs 6%, respectively; p<0.001). Males were more likely to be underweight (31% vs 16%), and females to
be overweight (18% vs 5%); p<0.001 in both cases.

12

Proportion of population defined as having abnormal LFTs varies according to the reference range that is applied

The proportion of the population falling above the upper limit of normal (ULN) for each parameter is 15 16 shown in Table 1, with ALT, AST and GGT distributions in Fig 1A-C (full data for all LFTs are shown in 17 Suppl Fig 1). These results highlight the different burden of disease that can be estimated according to 18 the reference range that is applied, with a higher proportion of the population falling above the ULN 19 when the ARR was applied compared to the LRR (Fig 1A, B). Most striking, for AST, 13% of the 50 population had a value that was deemed to be elevated based on ARR, compared to only 3% based on the LRR (Fig 1B). Using the ARR, ALT and BR were significantly more likely to be above the ULN in 51 52 males than in females, and ALP was more likely to be higher in females (p<0.001 in each case, Table 1). These sex differences were not apparent when the LRR was applied. OR for deranged LFTs and fibrosis 53 54 scores according to age and sex is shown in Suppl. fig 2.

55

56 The highest prevalence of liver fibrosis is predicted using the GPR score

We calculated APRI, FIB-4, GPR, RPR and S-index scores (Table 1). The estimated prevalence of 57 fibrosis was highest when based on GPR score (23.5%; Fig 1D), compared to FIB-4 (5.3%), APRI 58 59 (3.2%), S-index (3.9%) and RPR (0.1%). We excluded RPR scores from further statistical analysis 50 because so few individuals were classified as having an elevated score (we therefore did not have 51 statistical power to detect any factors associated with abnormal score). Because the APRI is derived using the ULN of AST, the proportion of the population classified as having a score consistent with liver 52 53 fibrosis changes according to whether the ARR or LRR is used (Table 1). Based on previous validation 54 among African individuals, there is evidence to suggest that GPR is the most accurate score for staging 55 liver fibrosis (12); applying this approach, there is a prevalence of almost 1 in 4 adults with liver fibrosis 56 in this population.

57

58 Evidence for the contribution of alcohol to liver disease

The prevalence of AST/ALT ratio >2, suggestive of alcoholic hepatitis, was 11% (888/8,099) (Fig 1E). There was a significant relationship between self-reported alcohol consumption and elevated AST/ALT ratio (p<0.001; Suppl Fig 3). However, 57% of participants with AST/ALT ratio >2 reported never having consumed alcohol (Fig 1E), possibly reflecting either under-reporting of alcohol use and/or other factors that underpin this pattern of LFTs. Self-reported alcohol consumption was associated with raised LFTs,

as follows: ALT (Adj. OR 1.33, 95% CI 1.09,1.63) AST (Adj. OR 1.53, 95% CI 1.30, 1.78) GGT (Adj.
OR 2.00 95% CI 1.69, 2.36), and with abnormal fibrosis scores, particularly GPR (Adj. OR 1.96, 95%
CI 1.52, 2.54). All ORs, adjusted ORs, their respective 95% confidence intervals and p-values are
shown in Table 2, and selected variables in Fig 2.

78

79 A raised GGT level in combination with AST/ALT ratio >2 can be used to increase the sensitivity of 30 detection of alcoholic hepatitis (8). GGT levels were significantly higher among males with AST/ALT ratio 31 \geq 2 (p<0.001), but there was no relationship between GGT and AST/ALT ratio in females (p=0.7); Suppl 32 Fig 4. This potentially indicates that alcohol is of more influence as a cause of an elevated AST/ALT ratio 33 in men than in women. There was no significant association between AST/ALT ratio ≥ 2 and the presence 34 of an elevated GPR score, predicting fibrosis (p=0.2; data not shown). We calculated population attributable risk (PAR) as a way to assess the relative contribution of different risk factors to the overall 35 36 burden of liver disease; Table 3. Overall, the most striking contribution arose from reported alcohol consumption, which accounted for 64% of abnormal S-index scores, 32% of elevated FIB-4 scores, and 37 19% of GPR abnormalities. 38

39

Abnormal LFTs and/or elevated fibrosis scores are associated with sex, age, and body mass index

)2 Females were less likely to have high fibrosis scores based on FIB-4 compared to males (Adj. OR: *3* 0.6), APRI (Adj. OR: 0.42), and S-Index (Adj. OR: 0.37) compared to males. FIB-4 score increased markedly with age: adults aged 40 - 49 (Adj. OR: 7.04), 50 - 59 (Adj. OR: 11.29), and adults >60 **)**4)5 years (Adj. OR: 25.15) were more likely to have a higher FIB-4 than individuals < 39 years. Elevated BMI was associated only with a rise in GGT (Adj. OR: 1.47). However, being underweight was)6 **)**7 associated with a more pronounced pattern of liver derangement, including elevations in ALT (Adj. OR: 98 1.40), AST (Adj. OR: 1.44), GGT (Adj. OR: 1.37), abnormal fibrosis scores (APRI Adj. OR: 1.72,) and **)**9 with raised AST/ALT ratio (Adj. OR: 1.61). 95% CI in each case are shown in Table 2.

)0

Relationship between BBV infection and liver disease

HIV infection was associated with abnormal liver function tests, with significant OR for increased ALT,
AST, ALP and GGT, as well as with raised GPR and S-index (on univariate and multivariate analysis;
Table 2). HBV infection was significantly associated with a rise in hepatic transaminases (OR for raised
ALT and AST 2.6 and 2.4 respectively, on multivariate analysis), and with liver fibrosis as measured by
APRI and GPR (OR 3.6 and 4.2 respectively, on multivariate analysis). We investigated the prevalence
of BBV infection among individuals with raised fibrosis scores. There was an association between the

presence of HIV or HBV and raised GPR (p=0.005) and S-Index (p<0.001). Therefore, GPR and S-Index may be the most sensitive markers of inflammation and/or fibrosis in the context of HBV or HIV infection. HIV and HBV were associated with a lesser proportion of liver disease than alcohol based on calculation of PAR (Table 3), but still contributed to elevations in both LFTs and fibrosis scores. The OR for deranged LFTs/fibrosis scores in the context of HIV or HBV infection is shown in Fig 2.

13

Liver disease of unknown aetiology

Among individuals with GPR>0.32, 33.8% had either BBV infection or had AST/ALT>2 (suggesting potential alcoholic hepatitis) (Fig 1D; Suppl Fig 5). However, this illustrates that 66% have raised fibrosis scores in the absence of a history of alcohol use, or HIV or HBV infection, suggesting that other factors unaccounted for in this study are likely to be contributing to the overall burden of liver disease. True prevalence of liver disease cannot be ascertained until reference ranges have been more carefully defined, correlating LFTs and fibrosis scores with the confirmed presence of underlying liver disease based on imaging or biopsy.

22

23 **DISCUSSION**

24 Liver disease is not well characterised in many parts of sSA despite the high prevalence of HIV and HBV, and potential exposure to hepatotoxins (1,3). In this study, we used cross-sectional data from a large 25 26 population cohort to estimate the burden of liver disease and to assess the possible impact of BBV 27 infection and alcohol consumption. The prevalence of abnormal LFTs depends on the reference range that is applied. The ARR suggests a higher prevalence of liver disease, therefore including more false-28 29 positives. The LRR was established based on individuals recruited from several countries across Africa 30 (Rwanda, Uganda, Kenya, Zambia) (16). While the values were derived from purportedly healthy adults, it is impossible to rule out a high background prevalence of underlying liver disease; in defining higher 31 values for the ULN of all tests, the LRR is more susceptible to false-negatives if used to screen for liver 32 33 disease.

34

LFTs are a blunt tool for assessment of liver health, with many potential confounding factors. This current study only accounts for a limited range of aetiological agents, and we did not include other potentially relevant factors such as Schistosomiasis infection, exposure to aflatoxin and use of traditional medications. Furthermore, LFTs were measured at only one point in time, potentially overcalling liver disease as a result of transient abnormalities.

11 Composite fibrosis scores have been developed with the aim of improving sensitivity of detection of liver 12 disease (29), but these scores also depend on platelet count which can be influenced by diverse factors. For example, in some African populations, thrombocytopenia is common due to infections such as 13 14 malaria, schistosomiasis, HIV or endemic parasites, as well as being influenced by inflammatory 15 conditions and certain drugs (9,10). We only had platelet counts for a sub-set of our study population, 16 limiting the number for whom we could determine APRI, FIB-4, GPR, S-Index and RPR scores. Data 17 surrounding the use of these scores in sSA is variable, but since in many low-income settings alternative 18 diagnostic equipment is unavailable, non-invasive approaches are vital to estimate liver damage and to 19 stratify clinical management decisions.

50

51 APRI and FIB-4 are currently recommended by the World Health Organisation (WHO) for assessment of hepatic fibrosis in patients with chronic HBV or HCV infection (30.31). However, there is evidence 52 53 showing that APRI is more accurate in assessing liver fibrosis among individuals with chronic HCV 54 compared to HBV infection (11). GPR and S-Index have been validated in small studies in sSA, and have been associated with improved classification of liver fibrosis in chronic HBV infection when compared to 55 APRI and FIB-4 (12–14). It is apparent that either larger studies, or indeed a meta-analysis, are required 56 to further assess the accuracy of these tests in different populations. GPR and S-index may be 57 58 worthwhile options to include in routine clinical practice to assess for liver fibrosis in African populations, 59 given the high burden of HBV in this continent (32,33). RPR has been used to detect fibrosis among individuals with chronic HBV in China (26), however this score was excluded from our analysis due to a 50 51 very small number of individuals falling above the suggested threshold for fibrosis.

52

53 The prevalence of AST/ALT ratio >2 in this population is 11%, suggesting potential alcoholic hepatitis 54 (34), concordant with a previous study in Uganda in which 10% of the population was estimated to have 55 alcoholic hepatitis (35), and with data from Uganda's non-communicable diseases risk factor survey which 56 estimated that almost 10% of Ugandan adults have alcohol use disorders (36). Data from emergency 57 attendances at Mulago Hospital in Kampala recorded 47% who reported alcohol use, while 21% and 58 10% met the study definitions of alcoholic misuse and alcoholic liver disease, respectively (35). Our 59 data are based on self-reported alcohol consumption so may underestimate the true extent of alcohol use. 70 We were unable to quantify alcohol intake or the nature of the alcohol consumed: this is challenging as 71 alcohol is often home-brewed or home-distilled from locally grown grains or fruits, and the alcohol content 12 may vary widely: e.g. the alcohol content of locally produced maize-based brews and liquor in Kenya 13 ranged from 2%-7% and 18%-53%, respectively (36). The global challenge of morbidity and mortality 14 associated with alcohol use is highlighted by recent studies from the Global Burden of Disease

consortium, in which alcohol ranks as the seventh highest cause of DALYs and deaths and worldwide
 (2), and together with HBV infection is a leading aetiological agent of liver cancer (37).

17

78 Abnormal LFTs are common in HIV infection for diverse reasons including direct cytopathic effects of HIV 79 on the hepatocytes, co-infection with other BBVs, opportunistic infection, malignancy, ART or other drugs, 30 or secondary to other factors such as alcoholism (38–41). Although a proportion of our study population 31 with fibrosis were infected with BBV (21.6%) and/or had a history of alcohol consumption (12.2%), there 32 was a residual proportion with scores suggestive of fibrosis and AST/ALT ratio >2 who cannot be 33 accounted for through either alcohol or BBV infection. This implies that other factors contribute towards 34 liver dysfunction in this population; a recently published article reported approximately 30% of liver 35 cirrhosis in Africa are not attributed to HBV, HCV, or alcohol misuse and could be as a result of other understudied factors such as NAFLD and use of traditional medicine (35). Aflatoxin exposure is 36 37 associated with liver cirrhosis and is among the major causes of hepatocellular carcinoma globally, with most cases reported from sSA. Within a previous study of the GPC, >90% of individuals had evidence of 38 39 exposure (42-44).

)()

In our population women were significantly more likely to be overweight women than men. This may be)1)2 associated with a higher incidence of NAFLD in women. However, typically only mild rises in ALT are **)**3 seen, and 80% of those with NAFLD have normal LFTs (45-47) so may not be identified within our current **)**4 dataset. Diagnosis of NAFLD therefore depends on ultrasound scan (USS); previous studies have consistently shown 70-80% of obese patients have NAFLD on imaging (46.48.49). These imaging **)**5)6 modalities were not available in our population, so we are unable to comment specifically on the possible prevalence of NAFLD. Interestingly, in this setting low body weight was more associated with deranged)7 98 LFTs and with biochemical evidence of liver fibrosis, suggesting a range of pathology that may contribute)9 to liver disease, including organ-specific effects of under-nutrition or stunting (37), as well as the effect of)() general systemic illness. Further studies are required to investigate the specific relationship between BMI)1 and liver fibrosis in African populations.

)2

In African populations, HCV infection has frequently been often over-reported due to a reliance on HCV antibody (HCV-Ab) testing, which detects not only current infection but also previous exposure, and is
 known to be susceptible to false positive results (28). In this cohort, 298/8145 (3.7%) individuals tested
 HCV-Ab positive, but among these only 13 were HCV RNA positive (overall prevalence 13/8145 =
 0.2%).

)8

Appropriate reference ranges for LFTs are necessary to contribute to an understanding of the burden and aetiology of liver disease. Further work is required to determine appropriate thresholds for the ULN of different parameters in different settings in sSA, and to determine which fibrosis score is most specific, through application of a more widespread approach to elastography and/or other imaging. At present, we have identified alcohol, HIV and HBV as risk factors for deranged LFTs and liver fibrosis, with a striking contribution made by alcohol, but further investigation is needed to determine other risk factors that contribute to liver disease in this setting.

29 FINANCIAL SUPPORT

The General Population Cohort is jointly funded by the UK Medical Research Council (MRC) and the UK Department for International Development (DFID) under the MRC/DFID Concordat agreement. The work on liver function also received additional funding from the MRC, (grant numbers G0801566 and G0901213-92157). JM is funded by a Leverhulme Mandela Rhodes Scholarship. PCM is funded by the Wellcome Trust, grant number 110110. LOD is funded by NIHR.

78 **FIGURE LEGENDS**

79

Fig 1: Liver function tests and hepatic fibrosis scores among adults in the Uganda General Population Cohort. Distribution of (A) ALT, (B) AST and (C) GGT. Dashed vertical lines indicate upper limit of normal (ULN) based on American reference range, ARR (blue) and local reference range, LRR (red), as shown in Suppl Table 2. Note no LRR for GGT. (D) Proportion of the population with an elevated GPR score, and among those with elevated GPR the proportion with a defined risk factor for fibrosis. (E) Proportion of the population with an elevated AST/ALT ratio, and among those with an elevated ratio the proportion with a self-reported history of alcohol intake.

37

Fig 2: Forrest plots to show odds ratio (OR) for host risk factors and elevated LFTs or fibrosis scores in the Uganda General Population Cohort. Data are presented for the final multivariate model for ALT, AST, APRI, GPR, and AST/ALT and we show variables that were independently associated with the outcome (statistically significant at the P<0.05 level after adjusting for other variables).

¹ALT - Alanine Transminase, AST - Aspartate Transminase, GGT - Gamma-glutamyl transpeptidase, ALP - Alkaline Phosphatase, BR - Total Bilirubin, FIB-4 - fibrosis 4, APRI - AST to Platelet Ratio Index, GPR - GGT to platelet ratio, AST/ALT ratio - Aspartate/ Alanine ratio, RR - relative risk, PAR (%) - population attributable risk percent, 95% CI denotes 95% confidence interval

² An S-index score of >0.3 is suggestive of liver fibrosis

³ Abnormal LFTs, according to ARR, are defined as test results outside of the following ranges: ALT (Male: 10 – 55 U/L, Female: 7 – 30 U/L), AST (Male: 10 – 40 U/L, Female: 9 – 32 U/L), GGT (Male: 8 – 61 U/L, Female: 5 – 36 U/L), BR (0 – 17 mmol/L), ALP (Male: 45 – 115 U/L, Female: 30 – 100 U/L)

⁴ Threshold used to predict liver fibrosis: APRI > 0.7. FIB-4 >3.25. GPR >0.32. RPR >0.825. S-Index >0.3

⁵ Adjusted for age, sex, alcohol consumption, HBV diagnosis, HIV status, and Body Mass Index.

⁶ A measure of zero indicates of no association between the risk factor and abnormal liver function tests. A positive value indicates that the exposure to the risk factor is a risk factor, while a negative value indicates that it is a protective factor.

[#] APRI score calculated using ULN of AST using African reference range

+ number of abnormal result, RR and PAR (%) are based on individuals who were classified as positives within each variable (ie. Alcohol drinkers, HIV positive, HBV positive)

Alcohol Consumption (Yes vs No)

BMI (Underweight vs normal) and a second second

U

BMI vs Norm)
