# 22 Abstract

- 23 Background: Per- and poly-fluoroalkyl substances (PFAS) are chemicals, detected in 95% of
- Americans, that induce osteotoxicity and modulate hormones thereby influencing bone health.
- 25 Previous studies found associations between individual PFAS and bone mineral density but did
- 26 not analyze their combined effects.
- 27 **Objective**: To extend weighted quantile sum (WQS) regression to a Bayesian framework
- 28 (BWQS) and determine the association between a mixture of serum PFAS and mineral density
- in lumbar spine, total and neck femur in 499 adults from the 2013–2014 National Health and
- 30 Nutrition Examination Survey (NHANES).
- 31 **Methods**: We used BWQS to assess the combined association of nine PFAS, as a mixture, with
- 32 bone mineral density in adults. As secondary analyses, we focused on vulnerable populations
- 33 (men over 50 years and postmenopausal women). Analyses were weighted according to
- 34 NHANES weights and were adjusted for socio-demographic factors. Sensitivity analyses
- 35 included bone mineral density associations with individual compounds and results from WQS
- 36 regressions.
- 37 **Results**: The mean age was 55 years old (Standard Error [SE]=1) with average spine, total and
- neck femur mineral densities of 1.01 (SE=0.01), 0.95 (SE=0.01), and 0.78 (SE=0.01) gm/cm<sup>2</sup>,
- 39 respectively. PFAS mixture levels showed no evidence of association with mineral density
- 40 (spine: β=-0.004; 95% credible interval [Crl]=-0.04, 0.04; total femur: β=0.002; 95%Crl=-0.04,
- 41 0.05; femur neck:  $\beta$ =0.005; 95%Crl=-0.03, 0.04) in the overall population. Results were also null
- 42 in vulnerable populations. Findings were consistent across sensitivity analyses.
- 43 **Conclusions**: We introduced a Bayesian extension of WQS and found no evidence of the
- 44 association between PFAS mixture and bone mineral density.

# 50 Introduction

51 As the population ages, low bone mineral density has emerged as a public health concern

- 52 because it is related to fractures, morbidities, hospitalizations, and premature mortality<sup>.1,2</sup>
- 53 Deterioration of bone mass differs between the sexes, with a higher prevalence in women.
- 54 About 10% of women over 50 years of age suffer from low bone mineral density, but only 2%
- of men of the same age have similar bone deterioration.<sup>3</sup> Traditional risk factors associated with
- 56 decreased bone mineral density include chronological age, family history of bone disease,
- 57 suboptimal high-impact physical activity, and smoking.<sup>4</sup> However, recent evidence suggests that
- 58 environmental exposures, including air pollution, lead, cadmium, and mercury, are associated
- 59 with lower bone mineral density and higher risks for osteoporosis.<sup>5-7</sup>
- 60

61 Per- and poly-fluoroalkyl substances (PFAS) are synthetic organic chemicals that have been

- 62 used extensively in industrial processes and commercial applications since the 1950s. These
- 63 chemicals are widely used and persist for long periods of time, resulting in increased levels of
- 64 environmental contamination.<sup>8,9</sup> The primary sources of human PFAS exposure include
- <sup>65</sup> migration from food packaging and cookware, drinking water, indoor air, and house dust.<sup>10</sup>
- 66 PFAS have been detected *in vivo* in human tissue samples,<sup>11,12</sup> in 95% of the U.S.
- 67 population.<sup>13</sup> PFAS are poorly metabolized and excreted slowly from the human body, with half-
- 68 lives of 4–8 years.<sup>14</sup> Previous human and animal studies showed that PFAS bioaccumulate in
- bones, with perfluorooctanoate (PFOA) being predominant.<sup>15,16</sup> Due to their limited susceptibility
- 70 to degradation and slow elimination by human bodies, human exposure to PFAS is of increasing
- 71 concern.<sup>17,18</sup>
- 72

The toxicity of PFAS to bones has been reported in human and animal studies, with high PFAS 73 74 concentrations associated with adverse skeletal outcomes, suggesting that bones are target tissues for PFAS toxicity.<sup>19</sup> PFAS are also endocrine-disrupting chemicals <sup>20</sup> based on their 75 hormonal modulation.<sup>21</sup> PFAS have been suggested to impact bone density via sex 76 hormones.<sup>22,23</sup> In rodents, exposure to PFAS was negatively associated with bone structure and 77 biomechanical properties.<sup>24</sup> Bone cell cultures showed increased bone resorption activity at low, 78 79 albeit environmentally relevant, PFAS concentrations in human bone marrow and peripheral blood-derived osteoclasts, through the effect of PFAS on the cytokine and clastokine profiles 80 during cell differentiation.<sup>19</sup> In human studies, bone PFAS concentrations and relative bone 81 82 volume have been correlated, but results are still inconclusive. In a few cross-sectional studies, 83 serum levels of a few PFAS were negatively associated with bone mineral density only in

women,<sup>19,21</sup> but findings for most compounds are null in the general U.S. population.<sup>19,21</sup> In 84 85 addition, all previous studies focused on the association between individual PFAS and bone 86 health outcomes; however, given their ubiquity and persistence, exposure likely occurs to many PFAS simultaneously. Those studies failed to account for the correlation structure among PFAS 87 88 or to consider PFAS exposure as a mixture.

89

90 Environmental health studies have applied weighted quantile sum (WQS) regression to assess

the mixture effect of multiple co-occurring factors and to identify the driving factors in the 91

92 mixture. Briefly, the WQS regression summarizes the overall exposure to the mixture by

estimating a single weighted index and accounts for the individual contribution of each 93

component of the mixture by using weights.<sup>25,26</sup> WQS regression splits the dataset into two 94

subsets, a training set (generally 40%) and a validation set (60%). In the first set, this approach 95

96 estimates the weights using an ensemble step and estimates average weights across B

97 bootstrap samples, and in the second subset it estimates the coefficient mapped to the mixture,

conditionally to the estimated weights.<sup>25-27</sup> This regression also requires a priori selection of the 98

99 directionality (positive or negative) of the coefficient associated with the mixture, and it

100 conditions on the weights in the weighted index for testing for significance using the hold out

validation set. As such, it does not provide diagnostics (confidence intervals, standard deviation, 101

and p values) about the weights of the components of the mixture.<sup>25,26</sup> 102

103

104 Here we proposed a novel Bayesian extension of the WQS regression (BWQS) to overcome its 105 limitations and to illustrate the method for assessing the combined association of several forms of serum PFAS as a mixture with bone mineral density in 499 U.S. adults from the 2013–2014 106 cycle of the National Health and Nutrition Examination Survey (NHANES).<sup>3,28</sup> We also stratified 107 108 our analysis for two vulnerable populations, men over 50 years of age and postmenopausal women.

109

# 110

#### Methods 111

#### 112 Study population

The NHANES is an ongoing survey of the noninstitutionalized U.S. adult population designed to 113

assess their health and nutritional status.<sup>28</sup> After providing informed consent, participants visited 114

a mobile examination center for standardized physical examination and collection of biological 115

116 specimens, which were used to assess exposure to environmental chemicals. All study

117 protocols were approved by the National Center for Health Statistics research ethics review

board <sup>3,28</sup>. In our analyses, we included the 2013–2014 NHANES cycle, in which both bone 118 119 mineral density and serum PFAS concentrations were measured and had not been previously studied. The 2013–2014 cycle also included four (linear and branched) PFAS isomers that were 120 not measured in any previous NHANES cycles. For both evaluations, the selection of NHANES 121 122 participants was random and designed to maintain the original NHANES characteristics, as previously described.<sup>13,29</sup> We excluded NHANES participants with missing information about 123 bone mineral measurements (N = 7060) or serum concentrations of PFAS (N = 1450) and those 124 with missing information on covariates (smoking and physical activity) or with bilateral 125 126 oophorectomy (N = 74). A total of 499 adults ( $\geq$ 40 years) was included in the main analysis. Secondary analyses were performed on 115 men over 50 years and 117 postmenopausal 127 women. Postmenopausal women included women over 60 years old, women who had not had a 128 129 menstrual period in the previous 12 months. We excluded from the analysis postmenopausal 130 women using hormone replacement treatment or taking parathyroid medication (N=45), due to 131 their influence on the endocrine system (Figure 1).

132

# **Bone mineral density assessment**

134 Bone mineral density (g/cm<sup>2</sup>) was measured using dual X-ray absorptiometry (Hologic QDR 135 4500A fan-beam densitometers; Hologic Inc., Bedford, MA, USA).<sup>3</sup> Antero-posterior lumbar 136 spine mineral density was scanned, and mean density was computed for the first through fourth 137 lumbar vertebrae. For the total and neck femur mineral density, the left hip was routinely 138 scanned. If a left-hip replacement or metal objects in the left leg were reported, the right hip was 139 scanned. Participants were excluded from the femur scan if they had bilateral hip fractures, 140 bilateral hip replacements, or pins. Participants weighing > 300 lbs (136 kg) or pregnant women 141 (defined by self-report or positive urine pregnancy test) were ineligible for the examination. Femur neck has been proposed as the reference skeletal site for defining osteoporosis in 142 epidemiologic studies,<sup>30</sup> whereas the total femur had been used as a benchmark for 143 osteoporosis in the national Healthy People program <sup>30</sup>. Each subject's scan was reviewed in 144 the Department of Radiology, University of California, using standard radiologic techniques and 145 NHANES protocols.<sup>3</sup> 146

147

# 148Serum PFAS measurements

149 Analysis of 12 PFAS in serum was conducted at the National Center for Environmental Health in

- a random one-third subsample of nonfasting participants; the NHANES characteristic
- 151 proportions were maintained.<sup>13,29</sup> Briefly, serum PFAS were measured using automated solid-

phase extraction coupled to isotope-dilution high-performance liquid chromatography- tandem 152 153 mass spectrometry.<sup>13</sup> The complete list of PFAS with their acronyms is included in Table S1. In 154 our analyses, we excluded four PFAS because their concentrations were below the limit of detection for more than 60% of samples (Table S1). For the remaining PFAS, when 155 156 concentrations were less than the limit of detection, a value equal to the limit of detection divided by the square root of two was used in the analyses. 157 158 159 Statistical methods and analyses 160 The Bayesian WQS (BQWS) regression Let the values for the correlated mixture components C be scored into quantiles (q<sub>ii</sub>) for the j-th 161 component (j = 1,..,C) and the i-th (i = 1,...,N) participant. We modeled the association between 162 the overall mixture and the outcome  $y_i$  using a generalized linear model framework 163 164  $g(\mu_i) = \beta_0 + \beta_1 [\sum_{i=1}^{c} w_i q_{ii}] + \gamma \mathbf{Z}$ 

where  $\mu_i = E(y_i)$ ,  $\beta_0$  is the intercept, and  $\beta_1$  is the coefficient mapped to the weighted index ( $\sum_{j=1}^{c} w_j q_{ji}$ ); g(.) is link function; and **y** is a vector of K coefficients mapped to the matrix of K covariates **Z**. Similar to WQS regression, we modeled the weight  $w_j$  for exposure to the j-th component as an arbitrary function, taking values between 0 and 1, and the sum of all mixture weights to be equal to 1.

170

The BWQS required specification of the link function, similar to the frequentist approach, and prior probability distributions on all parameters, which differs from WQS regression. The general assumption for each parameter was a weak or uninformative prior. However, more informative priors can be chosen when prior information is known. The link function assumed the following forms:

a) logit link function:  $y_i \sim \text{binomial} (1, \mu_i)$ , when Y was binary;

b) identity link function:  $y_i \sim Normal(\mu_i, \sigma^2)$ , with a noninformative prior for

178  $\sigma^2 \sim IGamma(0.1,0.1)$ , when Y was continuous.

179 Priors for the coefficients were uninformative or weakly informative and were summarized by

180 normal distributions with large variance [ $\beta_0$ ; $\beta_1 \sim Normal(0, 100)$ ;  $\gamma_k \sim Normal(0, 100)$ ] for each k =

181 1,...,K. Priors for the weights were modelled as a unit-simplex in order to have non-negative

weights ( $w_j \in (0,1)$ ) and to sum all weights to one ( $\Sigma w_j = 1$ ). The natural choice was the Dirichlet

distribution with the same density on each vertex for each component of the mixture; i.e.,  $\mathbf{w} =$ 

184  $(w_1, ..., w_C) \sim \text{Dirichlet}(\alpha = (\alpha_1, ..., \alpha_C))$ . The  $\alpha$  parameter can be selected a priori equal to 1, when

investigating the entire domain of the distribution uniformly. Results on simulated datasets,

186 showing the accuracy of the estimates of BWQS, are included in the supplemental material

- 187 (Figures S3-S5).
- 188
- 189 Statistical Analysis
- 190 We estimated the correlations among PFAS and then performed BWQS regression in which
- bone mineral density (continuous)—in lumbar spine, total femur, and femur neck—was
- associated with mixtures of PFAS. All analyses were adjusted for race/ethnicity (white, black,
- 193 Hispanic and other races), age (continuous), sex, physical activity (low-moderate or high),
- 194 poverty-income ratio (continuous), and smoking status (never or ever smoked). All variables
- 195 were selected based on previous association with the outcome.<sup>6,7,22</sup> Priors for all coefficients
- 196 were uninformative: Normal(0,100). Secondary analyses focused on two vulnerable
- 197 populations—men over 50 years old and postmenopausal women.
- 198
- As sensitivity analyses, we assessed the associations between the PFAS mixture and mineral
- 200 density in lumbar spine, total femur, and femur neck by using the frequentist WQS regression,
- for the overall population. We also used Bayesian linear regression to determine the association
- of each PFAS compound with bone mineral density in the overall population. We used R version
- 203 3.5.1 for all analyses. All analyses were weighted according to the NHANES weights,
- appropriately rescaled for the selected subsample, as described on the Centers for Disease
- 205 Control and Prevention website and in previous studies.<sup>31,32</sup>
- 206

# 207 Results

### 208 Study Population Characteristics

- Adults included in our main analysis were 55 years old on average (standard error (SE): 0.6),
- 210 mostly Caucasian (49%), never smoked (60%), reported physical activity below the optimal level
- 211 (66%), and had an average poverty-income ratio of 2.9 (standard error (SE): 0.9) (Table 1). On
- average, spine and (total and neck) femur mineral densities were 1.01 (SE: 0.01), 0.95
- (SE:0.01), and 0.78 (SE:0.01) g/cm<sup>2</sup>, respectively, in the adult population. Bone mineral density
- was different by sex, with postmenopausal women having lower density (p<0.05). In all groups,
- 215 serum concentrations of the linear and branched PFAS isomers (NPFOS, NPFOA, and
- 216 MPFOS) were higher than all other PFAS levels (PFHS, PFNA, PFDE, MPAH, and PFUA)
- 217 (Table 1). All serum PFAS concentrations were positively correlated with each other and
- showed similar patterns across populations (Figure 2).
- 219

# 220 BWQS regression characteristics

221 We employed BWQS regression to identify the association between the mixture of PFAS in

- subjects' serum and bone mineral density in spine, total and neck femur, in all adults together
- and in the most vulnerable populations separately.
- 224

225 PFAS concentrations were categorized into quartiles, and we set the main parameters of the

- Hamiltonian Monte Carlo chain to optimize the accuracy and speed of the models. In total, we
- set 1000 iterations, of which 500 were burn-in and 3 were thinned. All parameters showed no
- 228 autocorrelation between subsequent iterations, and the potential scale-reduction statistics,
- which were approximately equal to 1 for all estimated parameters, showed convergence of the
- chain to the equilibrium distributions (Table S2).
- 231

# 232 Results in the overall adult population

- In the overall adult population there was no evidence of association between the PFAS mixture
- and bone mineral density in lumbar spine ( $\beta$ =-0.004, 95% credible interval [CrI]: -0.04, 0.04)
- 235 g/cm<sup>2</sup>, total femur ( $\beta$  =0.002, 95% CrI: -0.04, 0.05) g/cm<sup>2</sup>, or femur neck ( $\beta$ =0.005, 95% CrI: -
- 236 0.03, 0.04) g/cm<sup>2</sup>. Components of the mixture contributed approximately equally to the mixture
- in the outcomes for the overall population (Figures 3A, 4A, and 5A; Table S2).
- 238

# 239 Sensitivity analyses in the overall adult population

- 240 Results from sensitivity analyses using the frequentist WQS approach, assuming a negative
- direction between PFAS mixture and bone mineral density, were similar to those of BWQS. We
- found no associations between the PFAS mixture and all outcomes (lumbar spine:  $\beta$  = -0.01, p =
- 243 0.69; total femur:  $\beta = -0.01$ , p = 0.51; femur neck  $\beta = -0.004$ , p = 0.82) using the validation hold
- out set of 70% (Figure S1, Table S3). Individual PFAS analyses showed a weak negative
- association among MPFOS and all bones (lumbar spine: -0.02, 95% Crl: -0.03, -0.009; total
- 246 femur: -0.01, 95% Crl: -0.02, -0.003; and femur neck -0.01, 95% Crl: -0.02, -0.004), whereas
- 247 PFNA was positively associated with total femur (0.04, 95% Crl: 0.01, 0.06) and neck femur
- 248 (0.03, 95% Crl: 0.01, 0.05) (Figure S2, Table S4). However, those associations did not persist
- 249 after correcting for multiple comparisons (data not shown).
- 250
- 251 Results in men over 50 years old and in postmenopausal women
- 252 There was no evidence of an association between the PFAS mixture and bone mineral densities
- 253 in men over 50 years old (lumbar spine:  $\beta$  =0.01, 95% CrI: -0.05; 0.08; total femur  $\beta$  =0.01, 95%

- 254 Crl: -0.04, 0.07; and femur neck  $\beta$  =0.02, 95% Crl: -0.04, 0.07) or in postmenopausal women
- 255 (lumbar spine  $\beta$  =0.00, 95% Crl: -0.08, 0.08; total femur  $\beta$  =0.02, 95% Crl: -0.04, 0.08; and
- femur neck  $\beta$  =0.02, 95% CrI: -0.03, 0.08). The contribution of all mixture components was
- similar across bones and across populations (Figures 3-5 panels B and C; Table S2).
- 258

# 259 Discussion

- We extended the WQS regression under a Bayesian framework and determined the combined association of eight PFAS with bone mineral density in lumbar spine and total and neck femur in a survey representative U.S. adult population in the years 2013–2014. The main BWQS characteristics include diagnostic statistics for all estimated parameters, and BWQS does not require a priori selection of the directionality of the coefficient associated with the mixture or splitting the original dataset, thus overcoming a few limitations of the frequentist approach.
- The application of our novel method showed no evidence of the association between serum
  concentration of PFAS mixture, composed of linear and branched PFOS and PFOA isomers
  (NPFOS, NPFOA, and MPFOS) and PFHS, PFNA, PFDE, MPAH, and PFUA, and bone mineral
  density in lumbar spine and total and neck femur. The contribution of each compound was
  similar across bones. Results were also consistent using the frequentist WQS approach and
  Bayesian linear regressions.
- 273

274 Our results confirmed prior findings showing null associations between PFAS exposure and 275 bone health in the overall adult U.S. population. Serum concentrations of individual PFAS, 276 namely, PFOA, PFOS, PFHS, and PFNA, were not associated with mineral density in spine and total and neck femur in the overall adult population in the 2009–2010 NHANES cycle.<sup>22</sup> 277 278 Previous findings showed that associations between a few individual PFAS compounds and 279 bone mineral density were negative and significant in women only, with higher concentrations of PFOA, PFOS, PFHS, and PFNA associated with lower bone mineral density and with a higher 280 risk osteoporosis in women.<sup>22</sup> However, those analyses ignored the correlations among those 281 compounds and did not consider PFAS as a mixture, thereby increasing the number of false 282 283 positives among significant results.

284

Epidemiological studies support the hypothesis that PFAS are endocrine disruptors. PFAS modulate thyroid and sex hormone concentrations, which play a critical role in bone remodeling and health <sup>33</sup>. Chronic PFAS exposure was associated with suppressed serum thyroxine and

triiodothyronine (T3) levels in human studies <sup>34,35</sup> and with altered responses to T3 in a T3-288 dependent cell line in vitro.<sup>36</sup> A cross-sectional study of adult NHANES participants <sup>35</sup> reported 289 290 that serum PFHS was positively associated with subclinical hyperthyroidism in women, which is a risk factor for decreased bone mass.<sup>37</sup> PFAS also interfere directly with estrogen and 291 292 androgen receptors, disrupting the biological effects of sex hormones and leading to reduced fecundity in women and delayed puberty in boys, both of which are associated with lower bone 293 mineral density later in life.<sup>23,38</sup> In studies of women's health, PFAS were associated with 294 decreased production of estradiol and progesterone, which are essential hormones for bone 295 296 health due to their promotion of osteoblast activity. Based on this body of literature, the PFAS mixture, mediated by endocrine receptors, might affect bone mineral density, but further studies 297 298 with longitudinal design are required to address this problem.

299

We also found no evidence of an association between the PFAS mixture and bone mineral density in vulnerable populations, including men over 50 years old and postmenopausal women. However, our results could have been limited by a small number of participants (n = 115 and 117, respectively). Also, men and women in this study were not asked whether they attempted to prevent bone deterioration by changes in lifestyle, such as using supplements or alternative treatments or eating a healthier diet.

306

307 PFOA and PFOS, both of which were previously associated with bone mineral density in women 308 <sup>19,22</sup> were analyzed and decomposed in linear and branched isomers in our analyses, and we 309 could not confirm previous results for those compounds. Due to the cross-sectional design of our study, we could not rule out whether it was reverse causation and PFAS exposure preceded 310 the outcomes or bone mineral status affected the response to exposure <sup>39</sup>. It is also possible 311 312 that our results may have been limited by the smaller number of participants (n=499) than other study showing an association between the exposure of a few PFAS and bone mineral density 313 (n=1914).<sup>22</sup> Further studies with longitudinal design and larger sample size could help to 314 disentangle the underlying mechanism linking PFAS exposure and bone health in older adults. 315 316

The strengths of our study include a novel statistical approach, which accounted for the correlation among co-occurring PFAS and provided information about the overall adverse associations of PFAS and bone density. We used a sample that is known to represent the U.S. population in the years 2013–2014, and we relied on PFAS concentrations and bone mineral

321 density levels that were validated and compared across NHANES cycles.

- 323 **Conclusions**. This is the first study to assess the relationship between exposure to a mixture of
- 324 PFAS and bone mineral density at three bone sites. The novel Bayesian WQS approach
- 325 identified both the overall association between PFAS mixture with bone mineral density and the
- 326 contribution of each PFAS to the mixture. The serum PFAS mixture showed no association with
- 327 mineral density of the lumbar spine and total and neck femur in the NHANES adult population in
- 328 the years 2013–2014.

445 See Table S1 for PFAS abbreviations. \* NHANES sampling weights were applied for calculation

446 of demographic descriptive statistics and therefore Ns for frequencies represent the weighted447 sample size.

- 449 Figure 1: Selection of the National Health and Nutrition Examination Survey (NHANES)
- 450 participants. Per- and poly-fluoroalkyl substances (PFAS).

- 452 **Figure 2.** Correlation between serum perfluorinated compounds (PFAS) across the overall adult
- 453 population, in men over 50 years old, and in postmenopausal women.
- 454 Color and shape of each elipse reflect the correlation between two compounds.

Figure 3. Estimates of the 1) association between lumbar spine mineral density and the
perfluorinated compound (PFAS) mixture and estimates of 2) mixture composition: weights
(percentage rescaled between 0 to 1) with 95% credible intervals for each mixture component in
A) the overall population, B) men over 50 years old, and C) postmenopausal women.
BMD = Lumbar spine bone mineral density adjusted for race/ethnicity, age, sex, physical

462 activity, poverty-income ratio, and smoking status.

463

Figure 4. Estimates of the 1) association between lumbar spine mineral density and the
perfluorinated compound (PFAS) mixture and estimates of 2) mixture composition: weights
(percentage rescaled between 0 to 1) with 95% credible intervals for each mixture component in
A) the overall population, B) men over 50 years old, and C) postmenopausal women.
BMD = total femur bone mineral density adjusted for race/ethnicity, age, sex, physical activity,

472 poverty-income ratio, and smoking status.

476 **Figure 5.** Estimates of the **1)** association between total femur mineral density and the

477 perfluorinated compound (PFAS) mixture and estimates of 2) the mixture composition: weights
 478 (percentage rescaled between 0 to 1) with 95% credible intervals for each mixture component in

479 A) the overall population, B) men over 50 years old, and C) postmenopausal women.

BMD = femur neck bone mineral density adjusted for race/ethnicity, age, sex, physical activity, poverty-income ratio, and smoking status.
