7 **Abstract**

8 The COVID-19 epidemic which began in China last year has expanded worldwide. A
9 flexible SEIRD epidemiological model with time-dependent parameters is applied to modeling
10 the pandemic. The value of the effective reproduction ratio is varied to quantify the impact of
11 quarantines and social distancing on the number of infections and deaths, on their daily changes.
12 and on the maxima in these daily rates expected during the epidemic. The effect of changing R_{eff}
13 is substantial. It ought to inform policy decisions around resource allocation, mitigation
14 strategies and their duration, and economic tradeoffs. The model can also calculate the impact of
15 changes in infectiousness or morbidity as the virus mutates, or the expected effects of a new
16 therapy or vaccine assumed to arrive at a future date. The paper concludes with a discussion of a
17 potential endemic end of COVID-19, which might involve times of about 100 years.

18 **Introduction**

19 The epidemic of novel coronavirus disease (COVID-19) that began in China in late 2019
20 has expanded rapidly to over 220 countries and all U.S. states, and upended the lives and
21 livelihoods of much of the world’s population. Over ten million cases and more than 500,000
22 deaths have been reported worldwide, of which 2.7 million and 128,000 respectively in the

23 United States as of July 1, 2020 (1). The pandemic and associated community mitigation
24 measures, have had a large negative economic impact as well. The virus could trim global
25 economic growth by 3.0% to 6.0% in 2020, with a partial recovery expected in 2021 (2).
26 Unemployment in the United States temporarily surged to levels not seen since the 1930s.
27 Further, the epidemic is expected to exacerbate global poverty. It might push millions of people
28 in the developing world, such as in India, Sub-Saharan Africa and South Asia, into extreme
29 poverty (3).

30 Planning for the pandemic, keeping supply chains open, caring for the sick, and searching
31 for effective therapies and vaccines have diverted the attention of healthcare professionals,
32 researchers, planners, and essential workers around the world. Institutions such as the CDC in
33 the United States are developing and refining COVID-19 scenarios designed to inform decisions
34 by public health and other government officials (4). These aim at helping to evaluate the effects
35 of mitigation strategies such as quarantines and social distancing, as well as with hospital
36 resource allocation. Each scenario is based on a set of numerical values for the biological and
37 epidemiological characteristics of COVID-19. These values — called *parameter values* — can
38 be used in mathematical and statistical models to estimate the possible effects of the epidemic in
39 different regions. They are being updated and augmented over time, as more is learned about the
40 epidemiology of COVID-19.

41 Here I outline a differential equation-based SEIRD model with time-varying parameters
42 and apply it to COVID-19 epidemic data. I discuss some of the potential implications of
43 community mitigation strategies and their weakening in order to reopen the economy. This
44 modeling approach is able to follow the entire development of an epidemic, from inception to
45 eradication or endemic equilibrium, if desired. The model helps quantify tradeoffs in terms of

46 additional cases and deaths in a given region and their maximum rates of increase, expected to
47 result from a weakening of social distancing, or “reopening”. It can also be used to assess the
48 impact of changes in a pathogen’s infectiousness or morbidity over time.

49 **Model and parameters**

50 SIR and SEIR compartmental epidemiological models have been studied for nearly one
51 hundred years. The term “compartmental” may have originated by analogy to trains or ships,
52 essential modes of transportation in the first part of the twentieth century. In the non-autonomous
53 SEIRD model discussed here, a population is divided into five non-overlapping classes, known
54 as *compartments*:

- 55 • S, susceptible hosts;
- 56 • E, exposed hosts, presumed to be latently infected but not yet infectious;
- 57 • I, infectious hosts;
- 58 • R, hosts recovered from the exposed and infectious population and,
- 59 • D, hosts deceased due to the infection

60 This approach leads to a system of five ordinary differential equations in the compartmental
61 variables, with time-dependent model parameters as coefficients. Shown in the Appendix, the
62 equations describe the time evolution of each of the above-mentioned population groups. Key
63 inputs to the model, defined in the Appendix, are the pathogen’s *basic reproduction number*, R_0 ,
64 or a closely related parameter, the *effective reproduction ratio*, R_{eff} . From these the transmission
65 rate from Susceptible to Exposed is calculated. Other required data are the transition rates from
66 each group to the next. An E host can either get infectious (move to I) or recover (move to R),
67 and an I host can either move to R (recover) or move to D (die from the disease). All Recovered
68 hosts are assumed to be immune, or “removed” from the epidemic, although it is possible to

69 relax this assumption. Hosts in all groups but D can also die for reasons unrelated to the
70 infection, at an average rate. Finally, a gross birth rate for the Susceptible group is specified, and
71 often set to the same value as the death rate unrelated to the infection (“steady state”). Such a
72 SEIRD model would be described as an *open-population model in steady state*. All of the model
73 parameters can vary with time, which affords the model a great deal of flexibility.

74 The starting point of the calculation (“time zero”) is specified by the fraction of the
75 population, I, infectious at that time (typically very small, e.g. one per million) while S is nearly
76 1.0 for a new epidemic. Any other starting point is also possible. Expressed as fractions of the
77 overall population, $S + E + I + R + D$ should add up to 1.0 at all times for steady-state models.
78 This provides a check on the accuracy of the numerical solution. All calculations were performed
79 in the **R** Statistical Environment (5). The differential equations were easily integrated out to 100
80 years using the `ode` function in **R** (6) (7) (8) in order to explore the long-term behavior of the
81 solutions. For practical uses, the focus is on the first year or two.

82 A rapidly growing set of reports on the COVID-19 infection parameters is becoming
83 available online. Table 1 lists those used in this study (9) (10) (11) (12) (13) (14) (15) (16)

84 [Table 1 about here]

85 The model allows the study of an epidemic from beginning to end. All of the model
86 parameters can vary with time to reflect, for example, a change in social distancing, a mutation
87 that alters the pathogen’s infectiousness, or a reduction in morbidity expected from a new
88 therapy available as of some point in the future. Coupled with a modern differential equation
89 solver (8), the model generates accurate results in seconds, which makes it feasible to perform
90 sensitivity analyses with respect to one or more of the parameters used, as shown below in

91 Figure 3. Models based on local data could be run and the results easily aggregated as needed, in
92 order to increase the granularity of predictions as data availability permits.

93 **Results**

94 Figures 1 and 2 present the results of two runs with identical parameters, except as
95 follows. In Figure 1 there is no attempt to slow down the infection rate with quarantine or social
96 distancing, and R_{eff} is 4.0 throughout. The run in Figure 2 uses a R_{eff} of 4.0 up to 0.2 years (2.4
97 months) into the epidemic, at which point it goes down to 2.0 until 0.4 years (4.8 months), to
98 simulate the potential effect of a quarantine extending for a bit over two months. A modified
99 reopening with R_{eff} of 3.0 is assumed for all subsequent times. Shading is used to highlight the
100 three time periods. The numbers inside each plot show the maximum value and/or end value of
101 the dependent variable, as relevant. The last two plots in each figure are examples of *phase-*
102 *space plots*, or *phase portraits* (17) (18); see also (19) and are discussed near the end of the
103 paper.

104 Each plot in Figure 2 should be compared with the corresponding plot in Figure 1. This
105 shows that, applied at an opportune time, the quarantine succeeds in slowing down the infection
106 (“flattening the curve”). The maximum values in the Exposed, Infected and daily death rate
107 categories, all decrease by better than 50%. The impact on cumulative deaths and Recovered is
108 less marked, as the epidemic is slowed down but not stopped (since R_{eff} remains greater than 1.)

109 Figure 3 shows the variation in the maximum daily infection rate with R_{eff} and with the time
110 at which this maximum is estimated to occur. These are the curves in red. Because the infection
111 probability increases with R_{eff} , the larger maxima occur at correspondingly shorter times. The
112 curves in blue show similar results for the estimated maximum daily death rate, or new deaths
113 per day. As can be seen from Figure 3 and Table 2, the effect of a change in R_{eff} on these
114 maximum daily rates is quite large. This type of information could be used to assess whether a

115 relatively early weakening of quarantine and social distancing in a given region, leading to a
116 substantial increase in R_{eff} , would result in an acceptable number of additional casualties.

117 [Table 2 about here]

118 Figure 4 depicts the results of the run at $R_{\text{eff}} = 4.0$ when integrated out to 100 years. The
119 use of logarithmic time as covariate allows the plot to cover a long time period and still show the
120 early part of the epidemic in detail. Beginning at time near 30 years, *the model predicts a series*
121 *of increasingly less severe resurgences of the epidemic.* Periodic and seasonal epidemic
122 recurrences are well known and have been studied using SIR-class models, both autonomous and
123 demographically forced (17) (18). The timing of the COVID-19 recurrences observed here varies
124 with the birth and death rates used, B and μ . Why? Every year a certain proportion of the
125 population dies for reasons unrelated to COVID-19, and a similar number of people are born, all
126 of which into the Susceptible population — certainly true after maternal immunity, if any,
127 disappears. Assume the disease is not eradicated, the pathogen has not lost its virulence, and no
128 effective vaccine has been found. In time the Susceptible group becomes large enough for the
129 virus to propagate again, albeit at a slower pace since some of the hosts it would encounter
130 would be immune. Eventually the proportion of Susceptible and Infected hosts approach constant
131 (equilibrium) values, at which point the epidemic becomes endemic. This is shown in the bottom
132 right-hand plot of Figure 4, a phase portrait, where time increases as the curve is traced in a
133 counterclockwise direction. Over the years the epidemic behaves like a damped oscillator, whose
134 dampening is related to the variation in “herd immunity” over time. Endemic equilibrium is
135 reached in approximately 100 years. Doubling B and μ would decrease the time to equilibrium
136 by about half.

137

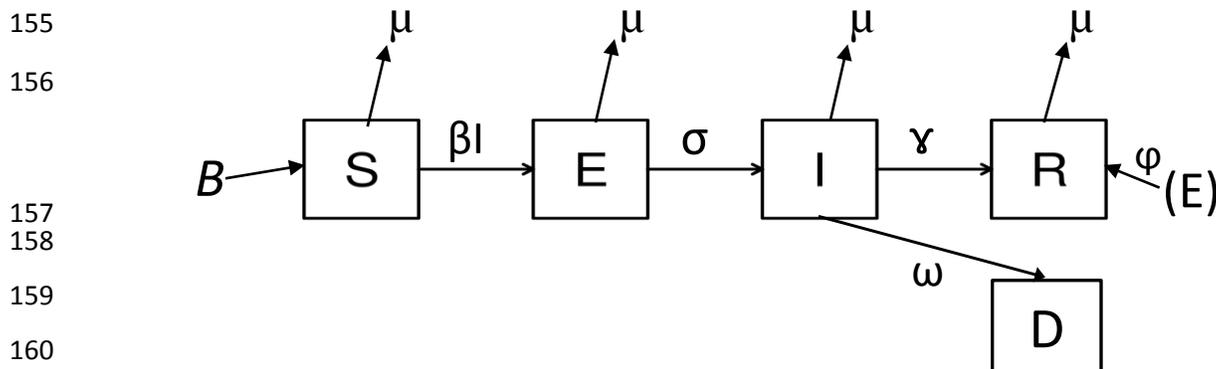

138 **Discussion**

139 A SEIRD epidemiological model with time-dependent parameters was presented, able to
140 follow an epidemic from inception to eradication or endemic equilibrium, and applied to
141 COVID-19 data. By varying the value of the pathogen’s effective reproduction ratio, the model
142 was used to assess the impact of quarantine and social distancing on the number of infections and
143 deaths, on their daily changes (“new infections per day”, “new deaths per day”) and on the
144 maxima in these daily rates expected during the epidemic. The effect of changing R_{eff} is
145 substantial and ought to inform policy decisions around resource allocation to hospitals,
146 appropriate mitigation strategies and their duration, and economic tradeoffs. Since all parameters
147 can vary with time, the model is also able to quantify the effect of a change in the pathogen’s
148 infectiousness or morbidity as the virus mutates, or the expected effects of a new therapy or
149 vaccine arriving at some future date. Finally, the long-term potential endemic end of COVID-19
150 absent eradication is discussed which, the model suggests, might involve times of the order of
151 100 years.

152

153 **Appendix**

154 SEIRD model diagram and its differential equations

162

$$\frac{dS}{dt} = B - (\beta I + \mu)S$$

163

$$\frac{dE}{dt} = \beta I S - (\sigma + \mu + \varphi)E$$

164

$$\frac{dI}{dt} = \sigma E - (\gamma + \mu + \omega)I$$

165

$$\frac{dR}{dt} = \gamma I + \varphi E - \mu R$$

166

$$\frac{dD}{dt} = \omega I$$

167

168 The basic reproduction number, R_0 , is the average or expected number of secondary
169 cases one typical case would produce in a completely susceptible population (20) (21). The
170 precise relationship between the transmission rate, β , and the pathogen's R_0 is model dependent.
171 For the SEIRD model described, it is

172

$$R_0 = \frac{B\sigma\beta}{\mu(\gamma + \mu + \omega)(\sigma + \mu + \varphi)}$$

173 R_0 has the following interpretation: it is the product of the production rates of E and I per unit
174 contact, weighted by B/μ (22).

175 In this paper we define R_{eff} as $R_{\text{eff}} = (1-f) R_0$ where f is the fraction of the
176 Susceptible population that has been “removed” from the susceptible pool at a given time *through*
177 *interventions* such as quarantine, social distancing, or immunity due to a vaccine. (The model
178 already accounts for immunity in the Recovered group.) Other definitions of R_{eff} may differ. All
179 of the model’s parameters can be arbitrary (known) functions of time.
