37

38 **ABSTRACT**

39 Breast cancer is a polygenic disorder and is the leading cause of cancer related mortality among
40 women. Early-onset breast cancer (EOBC) is diagnosed in women prior to 45 years-of-age and is
41 associated with worse clinical outcomes, a more aggressive disease phenotype, and poor prognosis
42 for disease-free survival. While substantial progress has been made in defining the genetics of
43 breast cancer, EOBC remains less well understood. In the current study we perform a retrospective
44 analysis of data derived from *The Two Sister Study*. The use of alternate strategies for handling
45 age-at-diagnosis in conjunction with haplotype-based methods yielded novel findings that help to
46 explain the heritability of EOBC. These findings are validated through comparison against
47 discordant sibs from *The Two Sister Study* as well as using data derived The Cancer Genome Atlas
48 (TCGA).

49 INTRODUCTION

50 Breast cancer is the most frequently diagnosed oncogenic malignancy and a leading cause
51 of cancer-related mortality among women worldwide (1, 2). Early-onset breast cancer (EOBC)
52 accounts for approximately 5-10% of all new female breast cancer cases and young age at
53 diagnosis correlates with worse clinical outcomes (3, 4). Germline variants play a prominent role
54 in the etiology of breast cancer and an estimated 10-15% of women who develop breast cancer
55 report a familial history of the disease. Germline variants in *BRCA1* or *BRCA2* are observed in 15-
56 20% of familial breast cancer cases (5). Direct evidence for genetic modifiers of breast and ovarian
57 cancer risk for *BRCA1* and *BRCA2* mutation carriers has been provided through genome-wide
58 association study (GWAS) (6). Patients affected by EOBC exhibit shared patterns of gene
59 expression that differ from their older counterparts (7). These combined observations suggest a
60 genetic component contributes to EOBC although only a fraction of the heritability of EOBC has
61 been explained.

62 Deciphering the genetic basis for phenotypic heterogeneity in complex diseases remains a
63 major challenge. Single marker association studies often lack sufficient statistical power to support
64 the discovery of rare variants or epistatic interactions within a polygenic architecture. Haplotype-
65 based analysis is thought to have greater power than single marker association tests in the study of
66 complex disease (8-10). Haplotypes, which consist of a series of sequentially ordered single
67 nucleotide variants (SNVs), are a potentially more informative format for association testing than
68 single markers and may have improved sensitivity and specificity for discovery (11, 12).
69 Haplotype-based analysis has been used to gain insight in a wide array of complex disease models
70 including mood disorders, multiple sclerosis, orofacial clefting, and cancer (13-18). Moreover,

71 haplotype-based analysis has been effectively applied to investigate age-of-onset in human disease
72 although relatively few studies have specifically addressed EOBC (19-23).

73 Several approaches have been used to investigate the genetic regulation of breast cancer
74 age-of-onset. *The Two Sister Study* made use of a familial case-control design with affected cases
75 diagnosed ≤ 50 years-of-age and discordant sibs of EOBC patients defining a control population.
76 Parental samples were included in *The Two Sister Study* to allow for the identification of
77 maternally-mediated effects and Mendelian errors in transmission (24-26). Other studies have
78 instead used categorical thresholding with diagnosis at 35, 40, 45, and 50-years-of-age to define
79 EOBC populations contrasted against either unaffected familial controls or unrelated age-matched
80 controls (3, 27-29). Age-of-onset has further been evaluated in terms of phenotypic extremes by
81 comparing individuals diagnosed at ≤ 35 years-of-age against cancer-free controls at age ≥ 60 or
82 against an age-specific cohort diagnosed with breast cancer at ≥ 65 years-of-age (30, 31). Still
83 others have investigated breast cancer in terms of age-stratified risk or using quantitative trait
84 analysis to support discovery. Internally consistent logic has justified the use of these and other
85 study designs. Yet the genetic basis for EOBC remains poorly understood and more recent studies
86 have turned towards meta-analyses aimed at achieving sufficient statistical power to identify rare
87 variants with small effect size (32-34).

88 Design considerations for the study of complex polygenic disorders have been evaluated
89 across a range of disease models. For example, Peyrot and colleagues have convincingly argued
90 against familial trio designs when investigating complex disease traits with a polygenic
91 architecture or a lifetime risk $\geq 1\%$ (35). Reasons given included a potential for reduced statistical
92 power, ascertainment bias, and a significant underestimation of SNV heritability. Additional
93 considerations in sib pair study design include the potential for misclassification and/or

94 overmatching (36). Misclassification of discordant sibs presents a challenge primarily in cases
95 associated with pronounced variation in age-of-onset. Overmatching presents a more significant
96 challenge in complex disease models where discordant sibs are likely to share an indeterminate
97 number of disease-related alleles. As a result, allele-frequency differences between affected and
98 unaffected sibs are generally underestimated relative to randomly selected affected and unaffected
99 individuals (36). Recent investigation of polygenic risk in multiplex melanoma families indicated
100 that familial controls may carry a significantly elevated polygenic load relative to unrelated cases
101 or healthy controls and thereby introduce bias (37). Kerber and colleagues likewise argued that
102 familial studies should be approached with caution, particularly when investigating complex
103 diseases such as cancer where variable onset, incomplete genetic penetrance, gene-environment
104 interactions, and environmental phenocopies have a dramatic potential to impact disease
105 occurrence and phenotype (38). The authors further argued in favor of a case-only analysis for an
106 initial scan followed by more comprehensive analysis of regions surrounding initial hits using both
107 affected and unaffected study participants. In keeping with this reasoning, we speculated that a
108 comparison of younger and older patients diagnosed with breast cancer might provide insight into
109 the genetic architecture of breast cancer age-of-onset.

110 We performed a retrospective analysis of “*The Two Sister Study: A Family-Based Study of*
111 *Genes and Environment in Young-Onset Breast Cancer*,” hereafter referred to as “*The Two Sister*
112 *Study*.” *The Two Sister Study* is one of the longest standing and best characterized studies of early-
113 onset breast cancer and hence was chosen to establish proof-of-principle. Initial screening was
114 performed using a case-only design and haplotype-based association testing while treating age-at-
115 diagnosis as a categorical variable. Candidate regions identified through this initial screen were
116 subsequently evaluated against discordant sibs defined within *The Two Sister Study* by variance

117 partition analysis and haplotype-trend regression. Findings were validated using data derived from
118 phase III of the 1000 Genomes Project and mutation and The Cancer Genome Atlas (TCGA).

119 **RESULTS**

120 Our objective in this study was to investigate the genetic basis for EOBC. Access to *The*
121 *Two Sister Study* was obtained through the Database of Genotypes and Phenotypes (dbGAP;
122 accession phs000678.v1.p1). The demographics of the study population have been described
123 elsewhere (25, 26, 39). The original study compared patients affected by young-onset breast cancer
124 (age-at-diagnosis ≤ 50) with familial controls using a case-control design and affected status as a
125 binary outcome. Pertinent populations for the purpose of this study included 1,456 cases affected
126 by breast cancer and 525 discordant sibs.

127 For initial screening, the affected population was dichotomized by virtue of age-at-
128 diagnosis using statistical modules within the %findcut SAS macro. The %findcut macro
129 calculates thresholds for the dichotomization of continuous variables and plots a local linear
130 regression (LOESS) curve which may be used to determine whether dichotomization is appropriate
131 for the variable in question (40). While a continuous trait would be expected to produce a linear
132 trend line with a slope $\cong 0$, the LOESS curve generated while analyzing *The Two Sister Study* case
133 population failed to meet the assumption of linearity (**Supplemental Fig S1**). The observed slope
134 and steep bend in the LOESS curve exhibited characteristics of a categorical variable justifying
135 dichotomization of the affected population based upon age-at-diagnosis. Theoretical cutpoints
136 were calculated using the %findcut macro and the mean value was used to distinguish between
137 younger (diagnosis ≤ 45 years-of-age; N = 735) and older (diagnosis > 45 years-of-age; N = 721)
138 populations.

139 Candidate prioritization initially involved a comparison of the younger and older affected
140 populations using haplotype-based association testing with an expectation-maximization (EM)
141 algorithm and a dynamic window size of 10 kilobases (kb) (**Fig 1a**). Quantile-quantile plotting
142 verified that the resulting data was normally distributed (**Supplemental Fig S2**). Several peaks
143 were observed by Manhattan plot (**Fig 1a**) with 6 haplotypes located at chromosome 6:
144 111,936,275-111,964,664 surpassing the threshold for genome-wide significance ($p \leq 5 \times 10^{-8}$).
145 This preliminary analysis identified 762 haploblocks representing 4,126 haplotypes (**Table 1**).
146 Upon filtering using $p > 5 \times 10^{-4}$ as a threshold for exclusion, 322 haplotypes within 282
147 haploblocks spanning 64 discrete autosomal regions were retained. Of these 64 regions, 15 were
148 associated with a single haploblock and 49 included two or more adjacent haploblocks with block
149 clusters ranging from 2-14 haploblocks in length.

150 Fine mapping of the aforementioned chromosomal regions was performed using
151 haplotype-based association testing and sliding windows of 2-6 SNVs in length as previously
152 described by Mathias *et al.* (41). Assuming a panel of 684,126 variants and 3,420,615 independent
153 tests across all windows a Bonferroni corrected threshold for genome-wide significance was
154 calculated as $p \leq 2.92 \times 10^{-8}$ using the method described by Song *et al* (42). A single-locus mixed
155 model analysis was performed for comparison using an identity-by-state kinship matrix and an
156 Efficient Mixed-Model Association eXpedited (EMMAX) algorithm as implemented in Sequence
157 Variation Suite software (Golden Helix, Bozeman, MO). To facilitate direct comparison of single
158 marker and haplotype-based analyses, Manhattan plots were overlaid (**Fig 1b**). Only windows of
159 2, 4, and 6 SNVs in length were included within the composite plot for visual clarity. The
160 composite image indicated haplotype-based testing generally outperformed single marker
161 association testing and increasing haplotype window size generally correlated with improved

162 statistical strength. Haplotypes located at chromosome 6: 111,936,275-111,964,664 including the
163 rs17754910 marker consistently exceeded the threshold for genome-wide significance with the
164 most significant haplotype (GACGAA; $p \leq 3.34 \times 10^{-10}$) consisting of markers rs671271,
165 rs17754910, rs490080, rs1327199, rs9487771, and rs585057. Composite windows representing all
166 haplotypes of 2-6 SNVs in length were filtered selecting for haplotypes with a χ^2 p value $\leq 5 \times 10^{-5}$.
167 This filter was applied as an incremental step towards achieving our objective which was to
168 identify regions where increasing haplotype structure correlated with improved significance. In
169 total 466 haplotypes consisting of 417 unique variants spanning 165 unique haploblocks remained
170 (**Table 1; Supplemental Table S1**). Of the 165 haploblocks, ten were isolated and nonadjacent.
171 Five of these blocks were excluded from further analysis because: 1) the component SNVs were
172 represented in adjacent clusters (blocks 6611, 7202, 8926, and 9337); or, 2) the isolated block was
173 weakly associated with an existing cluster (block 7489). The remaining isolated haploblocks
174 (blocks 3738, 6951, 7182, 8759, and 9862) failed to exhibit a significant association with age-of-
175 onset based on regression analysis and hence were excluded from further consideration. The
176 remaining 155 haploblocks consisted of 264 unique SNVs and formed consecutive clusters
177 defining 33 discrete chromosomal regions (**Supplemental Table S2**). The most significant
178 haploblocks within each of the 33 chromosomal regions are defined in **Supplemental Table S3**.

179 Visualization of haplotype structure was performed using the “Graphical Assessment of
180 Sliding P-values” (GrASP) excel macro (41). The GrASP macro concisely depicts haplotype
181 windows of varying length with corresponding p values, providing an efficient means for
182 screening regions of interest while visualizing haplotype substructure. Of the chromosomal regions
183 examined using the GrASP macro, 13 exhibited improvement in statistical significance and
184 incremental changes in haplotype structure with increasing window size (**Table 1**). Composite

185 images reflecting sliding window p values and the relative position of functional elements within
186 candidate regions are depicted in **Fig 2**. Regions of interest exhibiting improved significance with
187 increasing window size were associated with *TP73*, *LYPD6B*, *KIAA1109*, *ADAD1*, *IL2*, a
188 regulatory enriched region on chromosome 6, *ARHGEF10*, *AGO2*, *CNNM1*, *LINC00941*,
189 *PPFIBP1*, and non-coding loci including *ALI60035.1* and the *NEK4P1* pseudogene. As displayed
190 in **Fig 2** the region defined on chromosome 6 was the only region to exceed the threshold for
191 genome-wide significance. The region defined on chromosome 6 is functionally enriched
192 consisting of predicted regulatory elements including promoter and promoter flanking regions,
193 multiple enhancers, CTCF binding sites, and putative transcription factor binding sites. The nearest
194 sequence element was *LINC02527* located within ~11 kb of the defined region on chromosome 6.
195 Other regions of particular note identified through this screen included *ARHGEF10* and *IL2* both
196 of which are listed within the COSMIC census of known cancer drivers. Odds ratios and 95%
197 confidence intervals for the aforementioned chromosomal regions are portrayed as a forest plot
198 comparing younger and older breast cancer populations in **Fig 3**. Positive correlations between
199 candidate haplotypes and younger breast cancer patients (diagnosis \leq 45 years-of-age) relative to
200 older breast cancer patients (diagnosis = 46-50 years-of-age) were associated with *LYPD6B*, the
201 long arm of chromosome 6, *AGO2*, *LINC00941*, and *PPFIBP1*. The most striking comparison was
202 associated with *LYPD6B* with an OR = 6.95 and a 95% CI of 2.47-19.51. Negative correlations
203 between candidate haplotypes and younger breast cancer patients (diagnosis \leq 45 years-of-age)
204 relative to older breast cancer patients (diagnosis = 46-50 years-of-age) were associated with *TP73*,
205 *ADAD1*, *IL2*, *ARHGEF10*, *CNNM1*, the long arm of chromosome 13, and the long arm of
206 chromosome 21.

207 Comparison of haplotype frequencies between siblings, however, failed to fully address
208 the potential for overmatching as previously described (36). Correction for hidden population
209 stratification through the use of kinship matrices provides an important and essential control in
210 genotypic analyses but may be more robustly controlled for through population-based haplotype
211 frequency analysis drawing upon data outside of the discovery population. Hence, we evaluated
212 haplotype frequencies observed within *The Two Sister Study* against phase III data from the 1,000
213 Genomes Project (**Fig 4**). Towards this end haplotype frequencies derived from The Two Sister
214 Study were compared to haplotype frequencies observed in African (AFR), American (AMR),
215 East Asian (EAS), and non-Finnish European (EUR) populations. Viewed within this context,
216 haplotype frequencies within *The Two Sister Study* were elevated in comparison to AFR and/or
217 AMR populations for *TP73*, the *KIAA1109* promoter, *ADAD1*, *IL2*, *ARHGEF10*, *CNNM1*, and
218 the long arms of chromosomes 6, 13, and 21. Eight haplotypes did not occur within the EAS
219 population. Minimal variation was observed in the non-Finnish EUR population relative to *The*
220 *Two Sister Study*.

221 Haplotype trend regression was used to analyze the aforementioned 33 autosomal regions
222 of interest in both affected (1,456 breast cancer patients) and unaffected (525 discordant sibs)
223 populations as originally defined within *The Two Sister Study*. Whereas visual representation of
224 data using the GrASP macro provided an intuitive sense of evolving haplotype structure, haplotype
225 trend regression provided robust measures of statistical significance. Full model permuted p values
226 indicated 14 of the 33 regions investigated were significantly associated with EOBC within the
227 affected population (**Table 2**). Conversely, haplotype trend regression failed to detect significant
228 associations between the candidate regions and discordant sibs. Haplomaps summarizing marker

229 distributions are presented in **Supplemental Figure S3** and marker characteristics are described
230 in **Supplemental Table S4**.

231 In an attempt to validate our findings, we first analyzed breast cancer expression data
232 obtained through cbiportal (43). The expression data included the “mRNA expression z-scores
233 relative to normal samples (log RNA Seq V2 RSEM)” file and included representing 994 donors.
234 Variance partition analysis was performed to evaluate associations between gene expression and
235 age-at-diagnosis. Summary findings indicated that expression of *AGO2*, *KIAA1109*, and *PPFIBP1*
236 was significantly associated with breast cancer age-at-diagnosis and explained 4.47% of age-
237 related variance within the population (**Table 3**).

238 Subsequent analysis was performed in an attempt to correlate gene-specific mutation types
239 with age-at-diagnosis. Due to the rarity of discrete mutation types the study population was
240 expanded to include 30 studies across various tissues that were accessed through cbiportal.
241 Pediatric studies were excluded from analysis and 20 years-of-age was applied as a cutoff to
242 exclude minors. Subpopulations were defined by the affected gene and type of mutation
243 (amplification, deletion, missense/truncating mutation). Significant associations linking age-at-
244 diagnosis to (candidate x mutation type) were identified by two sample Z-test (**Table 4**). The mean
245 age-at-diagnosis \pm standard deviation for controls was 60.2 ± 13.13 years-of-age. Significant
246 associations between age-at-diagnosis and gene-specific copy number variants involving
247 amplifications were observed in *ARHGEF10* (63 ± 10.86 ; $p = 0.029$); *CNNMI* (54.2 ± 11.61 ; $p =$
248 0.004); *LYPD6B* (57.5 ± 13.39 ; $p = 0.04$); and *TP73* (62.9 ± 10.38 ; $p = 0.021$). Significant
249 associations between age-at-diagnosis and gene-specific copy number variants involving deletions
250 were observed in *ADADI* (64.4 ± 10.06 ; $p = 0.0047$); *AGO2* (64.6 ± 11.02 ; $p = 0.022$); *CNNMI*
251 (66.1 ± 10.42 ; $p = 0.00011$); *IL2* (64.4 ± 10.06 ; $p = 0.0047$); *KIAA1109* (64.6 ± 9.57 ; $p = 0.0023$);

252 and *LYPD6B* (64.8 ± 10.36 ; $p = 0.00091$). Significant associations involving missense/truncating
253 mutations followed a trend similar to that observed in association with deletions as might be
254 expected in terms of functional consequence.

255 **DISCUSSION**

256 Our objective in this retrospective study was to gain insight into the genetics of EOBC
257 using existing data sets. We proposed to do so through a subtle rephrasing of the initial hypothesis
258 and by applying haplotype-based methods rather than single marker tests of association. *The Two*
259 *Sister Study* data set was chosen for retrospective analysis because it is among the best
260 characterized studies involving EOBC and because the data structure lends itself to formation of
261 alternative hypotheses. We believe there is a need to explore alternatives in the study of complex
262 disease in general because the greater portion of phenotypic heterogeneity in complex disease
263 remains unexplained. By way of example the investigation of breast cancer has resulted in the
264 identification of a handful of genetic drivers with large effect and more than 200 susceptibility loci
265 with minor effect explaining less than half of breast cancer heritability. Known drivers associated
266 with EOBC are less well defined. Yet EOBC accounts for an estimated 10% of all new breast
267 cancer cases among women and an estimated 15% of breast cancer deaths result from breast
268 cancers initially diagnosed prior to 45 years-of-age (3, 44).

269 *The Two Sister Study* made use of a familial study design to identify maternally-mediated
270 affects and germline associations with EOBC by contrasting breast cancer patients diagnosed prior
271 to the age of 50 against discordant siblings (25, 26). In the current study we addressed a different
272 question and hypothesized that candidate associations with EOBC might more readily be identified
273 by contrasting younger and older cases of breast cancer. This supposition is consistent with

274 arguments presented by Kerber and colleagues (38), although the merits of treating age as a
275 categorical variable remains a subject of debate (45-47).

276 Initial haplotype-based association studies to compare cases (age-at-diagnosis ≤ 45) and
277 controls (age-at-diagnosis = 46-50) yielded normally distributed results as determined by QQ plot.
278 Preliminary screening alone identified a single SNV exceeding genome-wide significance
279 (rs17754910; $p = 4.73 \times 10^{-9}$, FDR = 0.0016). Haplotype-based association testing and sliding
280 window analysis helped identify 33 chromosomal regions of interest, 13 of which exhibited
281 increasing haplotype structure in conjunction with improved measures of significance. The
282 qualitative observations resulting from sliding window analysis were subsequently corroborated
283 by haplotype trend regression with 14 of the 33 candidate regions achieving a permuted p value \leq
284 0.05. It should be noted that the only haplotypes to achieve genome-wide significance by means
285 of haplotype-based association testing included the rs17754910 SNV on chromosome 6 in a region
286 enriched with regulatory elements. The nearest sequence element approximately 11 kb upstream
287 of the rs17754910 SNV is the non-coding *LINC02527* RNA (chromosome 6: 111,900,306-
288 111,909,395). We note that alternating methylation patterns are observed within the *LINC02527*
289 promoter in various cancers including breast cancer (48). Other candidates identified by haplotype
290 trend regression included the known cancer drivers *IL2* and *ARHGEF10* (interleukin 2 and rho
291 guanine nucleotide exchange factor 10, respectively) neither of which have previously been
292 associated with an early-onset cancer phenotype. The remaining candidates identified by haplotype
293 trend regression may be broadly categorized in terms of known involvement in cancer, metastasis,
294 and age-of-onset in disease. *AGO2* (argonaute 2), *CNNM1* (cyclin and CBS domain divalent metal
295 cation transport mediator 1), *KIAA1109*, and *TP73* (tumor promoter 73) have been implicated in
296 breast cancer, metastasis, and disease age-of-onset (49-57). The noncoding *LINC00941* RNA,

297 *LYPD6B* (LY6/PLAUR Domain Containing 6B), and *PPFIBP1* (liprin-beta-1) have been
298 implicated in cancers that may or may not include breast cancer, have been implicated in
299 metastasis, but have no known association with disease age-of-onset (58-61). *ADADI* (adenosine
300 deaminase domain containing 1) has no known association with cancer but has been associated
301 with early-onset asthma and may have a role in childhood seizures. Last, the *NEK4P1* pseudogene
302 and the AL160035.1 sequence have no known associations with cancer, metastasis, or disease
303 onset. Though not addressed within the body of this study, we note that Ingenuity Pathway
304 Analysis associated *AGO2*, *ARHGEF10*, *CNNM1*, *IL2*, *KIAA1109*, *LYPD6B*, *PPFIBP1*, and *TP73*
305 with a single network centered around nodes formed by *TP53* and the estrogen receptor. We note
306 the obvious absence of *BRCA1/BRCA2* within the network and mention it here as an anecdote
307 worthy of speculation.

308 Haplotype frequency analysis within *The Two Sister Study* and phase III data from the 1000
309 Genomes Project yielded insight specifically with regard to the potential hazards of overmatching
310 in study design. As mentioned overmatching presents a potentially significant challenge in
311 complex disease models where discordant sibs are likely to share an indeterminate number of
312 disease-related alleles (36). If, as suggested by the current literature, hundreds of discrete
313 susceptibility loci control breast cancer occurrence and phenotypic expression, we must consider
314 the possibility that familial controls carry a greater burden of polygenic risk alleles without
315 necessarily experiencing disease occurrence. Because no single allele drives breast cancer
316 occurrence, it logically follows that differences in allele or haplotype frequencies between
317 discordant sibs may lack the capacity to distinguish between alleles associated with phenotypic
318 heterogeneity in complex disease. It is known that familial controls may carry a significantly
319 elevated polygenic load relative to unrelated cases or healthy controls creating an uncontrolled

320 source of bias in discovery (37). By way of example we note that haplotype frequencies are
321 elevated in discordant sibs relative to affected breast cancer patients for *TP73*, *IL2*, and
322 *ARHGEF10* (**Fig 3**). *IL2* and *ARHGEF10* are both listed within the COSMIC census of known
323 cancer drivers and it does not require a stretch of the imagination to consider that *TP73* might play
324 a role in breast cancer. Based solely upon haplotype frequencies observed in discordant sibs, it
325 would appear that all three haplotypes are negatively correlated with EOBC. Yet the observed
326 haplotype frequencies for these three genes within *The Two Sister Study* are elevated when
327 compared to the 1000 genomes phase III AMR population by 1.54-fold, 1.68-fold, and 1.82-fold,
328 respectively. The undefined element on chromosome 21 is elevated by 18.86-fold relative to the
329 AFR population although the very same haplotype is more abundant in discordant sib controls
330 relative to breast cancer patients diagnosed at ≤ 50 years-of-age.

331 Because this study was retrospective a replication of our findings would be challenging
332 without a prospective collection of new data, something which is beyond the scope of the current
333 study. In the absence of replication, we have attempted to validate our findings with supporting
334 evidence as a matter of due diligence. Towards this goal breast cancer gene expression data derived
335 from the TCGA pan-cancer study was evaluated using regression modeling and variance partition
336 analysis to identify correlations between gene expression and age-at-diagnosis. Earlier age-at-
337 diagnosis was associated with higher expression of *AGO2* ($p = 1.19 \times 10^{-4}$), *KIAA1109* ($p = 1.13$
338 $\times 10^{-5}$), and *PPFIBP1* ($p = 1.07 \times 10^{-3}$). These findings are consistent with prior studies involving
339 *AGO2* and *KIAA1109* and provide new evidence suggesting a potential association of *PPFIBP1*
340 expression in EOBC (50, 54). Under the assumption of an additive model, expression of these
341 three genes was calculated to explain a combined 4.47% of age-related variance within the study
342 population.

343 Subsequent validation involved the evaluation of age-at-diagnosis as a function of gene-
344 specific mutations drawing upon available data from 30 distinct cancer studies for statistical
345 purposes. Of the gene-specific mutations the vast majority were observed to result in a significant
346 increase in the mean age-at-diagnosis. We speculate that most of these mutations are unlikely to
347 be causally associated with late-onset disease and instead reflect the global accumulation of
348 damage as a secondary consequence of errors in DNA repair. The candidate genes *CNNM1* and
349 *LYPD6B* shared a unique feature, though, in that both exhibited bidirectionality of effect depending
350 upon mutation status. Gene amplifications affecting *CNNM1* and *LYPD6B* were associated with a
351 significantly lower mean age-at-diagnosis (54.2 ± 11.61 and 57.5 ± 13.39 years-of-age,
352 respectively). Deletions affecting *CNNM1* and *LYPD6B* were conversely associated with a
353 significant increase in mean age-at-diagnosis (66.1 ± 10.42 and 64.8 ± 10.36 years-of-age,
354 respectively). This bidirectionality of effect, we believe, is sufficiently compelling to warrant
355 further investigation of *CNNM1* and *LYPD6B* as contributory factors in EOBC.

356 Complex disease phenotypes remain a major challenge in the genomic sciences.
357 Frequentist strategies, based upon the assumption that more data will translate into more insight,
358 are currently in vogue and serve a valuable purpose. The identification of rare variants associated
359 with disease is a matter of sample size and ongoing efforts to integrate disparate data sets for meta-
360 analysis is a monumental challenge. Our objective in the current study is less ambitious and merely
361 asks if we can repurpose data to improve our understanding of complex disease. To that limited
362 extent, we have achieved our goal. We have identified a new candidate of genome-wide
363 significance with a potential role in EOBC. We have provided strong supporting evidence
364 justifying the pursuit of a handful of priority candidates with a potential role in EOBC. We have
365 identified two known cancer drivers with a potential involvement in disease onset. And, we have

366 highlighted conditions where frequentist analysis may lead to questionable conclusions in the
367 analysis of familial data. Data-mining, in this instance, suggests that there may be merit in re-
368 examining existing data and the assumptions made during initial inquiry.

369 METHODS

370 **Data: *The Two Sister Study*.** Discovery was performed using data derived from *The Two Sister*
371 *Study: A Family-Based Study of Genes and Environment in Young-Onset Breast Cancer* (accession
372 phs000678.v1.p1). Study contents were accessed under a Data Use Certification (DUC)
373 Agreement via the Database of Genotypes and Phenotypes (dbGAP). The dataset includes
374 genotypic, phenotypic, and demographic data for 1,456 patients, 525 discordant sib controls, and
375 an additional 1,359 controls. The demographics of the population have been described (25, 26,
376 39). The parent study described 1,458 patients. We believe two of these patients were erroneously
377 excluded from the present study during filtering to eliminate duplicate samples. Quality control
378 filtering of the corresponding genotypic data retained a total of 684,126 variants with a call rate \geq
379 0.99, a minor allele frequency ≥ 0.05 , and a Hardy-Weinberg p value $\geq 1 \times 10^{-6}$ within the older
380 “control” population.

381 **Data: cbiportal.** In order to validate initial findings clinical data spanning 30 studies representing
382 10,902 donors was accessed through cbiportal (43). A total of 220 donors were excluded due to
383 cross-study differences in the definition of donor age. An additional 23 donors diagnosed prior to
384 the age of 20 were excluded as minors. The studies were selected based on three criteria: 1) existing
385 evidence of an early-onset cancer phenotype within the tissue; 2) the availability of data defining
386 age-at-diagnosis; and 3) exclusion of pediatric studies. Composite data included the following
387 studies: Acute Myeloid Leukemia (OHSU) (62), Breast Cancer (METABRIC) (63, 64), Breast
388 Cancer (SMC) (65), Breast Fibroepithelial Tumors (Duke-NUS) (66), Breast Invasive Carcinoma
389 (British Columbia) (67), Breast Invasive Carcinoma (Broad) (68), Breast Invasive Carcinoma
390 (Sanger) (69), Breast Invasive Carcinoma (TCGA, PanCancer Atlas) (70), Cervical Squamous Cell
391 Carcinoma (TCGA, PanCancer Atlas) (71), Clear Cell Renal Cell Carcinoma (DFCI) (72),

392 Colorectal Adenocarcinoma (DFCI) (73), Colorectal Adenocarcinoma (TCGA, PanCancer Atlas)
393 (71), Esophageal Adenocarcinoma (TCGA, PanCancer Atlas) (71), Esophageal Squamous Cell
394 Carcinoma (ICGC) (74), Esophageal Squamous Cell Carcinoma (UCLA) (75), Kidney
395 Chromophobe (TCGA, PanCancer Atlas) (71), Kidney Renal Clear Cell Carcinoma (BGI) (76),
396 Kidney Renal Clear Cell Carcinoma (IRC) (77), Kidney Renal Clear Cell Carcinoma (TCGA,
397 PanCancer Atlas), Kidney Renal Papillary Cell Carcinoma (TCGA, PanCancer Atlas) (71), Liver
398 Hepatocellular Carcinoma (TCGA, PanCancer Atlas) (71), Lung Adenocarcinoma (OncoSG) (78),
399 Lung Adenocarcinoma (TCGA, PanCancer Atlas) (71), Ovarian Serous Cystadenocarcinoma
400 (TCGA, PanCancer Atlas) (71), Prostate Adenocarcinoma (Broad/Cornell) (79), Prostate
401 Adenocarcinoma (Fred Hutchinson CRC) (80), Prostate Adenocarcinoma (TCGA, PanCancer
402 Atlas) (71), Small Cell Carcinoma of the Ovary (MSKCC) (81), Uterine Carcinosarcoma (Johns
403 Hopkins) (82), and Uterine Corpus Endometrial Carcinoma (TCGA, PanCancer Atlas) (71).
404 Samples lacking mutation in any of the candidate genes were assembled into a control dataset (N
405 = 7026). In order to validate initial findings, experimental data sets were assembled on a per gene
406 basis and subcategorized according to mutation type (amplification, deep deletion, or
407 missense/truncating mutations).

408 **Data: The 1000 Genomes Project.** Genotypic data from phase III of the 1000 Genomes Project
409 was obtained through the Ensembl data portal Donor identification numbers were matched to
410 genotypic data in order to assemble haplotypes. Quantification of haplotype frequencies was
411 subsequently performed using the Haploview software package.

412 **Cutpoint optimization.** The %findcut SAS macro was used to calculate cutpoints as previously
413 described (83). The mean value was used as the cutoff for dichotomizing the case population in all
414 subsequent analyses.

415 **Association testing.** All association testing was performed using the Sequence Variation Suite
416 software package (Golden Helix, Bozeman, MO) and a custom workstation with dual Xeon Gold
417 12-core processors and 192 Gb RAM (Thinkmate, Waltham, MA). Genotypic data sourced from
418 *The Two Sister Study* was filtered to exclude variants with a call rate ≤ 0.99 , a minor allele
419 frequency < 0.05 , or extremes in Hardy-Weinberg disequilibrium within the control population (p
420 $\leq 1 \times 10^{-6}$). In order to identify regions of interest, haplotype-based association testing was
421 performed using an EM algorithm (50-iterations, convergence tolerance = 0.0001, frequency
422 threshold = 0.01) and a dynamic window size of 10 kilobases (kb). Covariates in the analysis
423 included race, family history of disease occurrence, and age-at-menopause. Regions of interest
424 were identified using a threshold of $p \leq 5 \times 10^{-4}$.

425 **Sliding window haplotype-based association testing.** Sliding window analysis was performed
426 essentially as described by Mathias *et al* (41). Genotypic data from patients affected by breast
427 cancer was filtered as described leaving a total of 684,126 variants for analysis. Sliding window
428 analysis was subsequently performed using windows of varying size (2-6 SNPs) to evaluate
429 unphased haplotypes. Analysis was performed using a case-control design and an EM algorithm
430 (50-iterations, convergence tolerance = 0.0001, haplotype frequency threshold = 0.01). Applied
431 test statistics consisted of a single test per sliding window and not the individual tests for each
432 haplotype. For comparison, a single-locus Efficient Mixed-Model Association eXpedited
433 (EMMAX) analysis was performed under an additive model using Sequence Variation Suite
434 software (Golden Helix).

435 **Manhattan plots.** Manhattan plots were generated by plotting of observed versus expected $-\log[p]$
436 values. A single plot was constructed using output from haplotype-based association testing with
437 a static window size of 10 kb for reference. A second composite plot was constructed by overlaying

438 the output from single marker association tests and sliding window association tests using windows
439 of 2, 4, and 6 SNVs in length.

440 **Graphical assessment of p-values from sliding window haplotype tests (GrASP).** GrASP is a
441 graphical tool for displaying p-values from sliding window tests (41). The Excel add-on produces
442 a simple graphic that simultaneously depicts the width of the sliding windows while using user-
443 specified color to specify varying levels of significance. GrASP allows the user to identify
444 regions/blocks of interest, based jointly on the absolute p-value of the tests from these windows
445 and the building of haplotypes of significance in the region. Graphical representations for regions
446 of interest were assembled and trimmed to display regions of increasing significance while
447 minimizing the length of flanking sequence falling below a threshold of $p < 5 \times 10^{-5}$. Assembled
448 images were presented within the context of functional genomic elements as defined within the
449 Ensembl human genome browser (GRCh38). GrASP is freely available for use at:
450 <http://research.nhgri.nih.gov/GrASP/>.

451 **Forest plot.** Odds ratios (OR) and 95% confidence intervals (95% CI) were derived from a single
452 overall test per sliding window, and not the individual tests of deviation for each haplotype.
453 Weighting was performed using $-(\log[p])$ as the weighting variable so that symbol size directly
454 correlated with significance. A Forest plot depicting the OR and 95% CI was generated using the
455 “DistillerSR Forest Plot Generator from Evidence Partners” web resource
456 (<https://www.evidencepartners.com/resources/forest-plot-generator/>).

457 **Haplotype trend regression.** Haplotype trend regression was performed using the Sequence
458 Variation Suite software package (Golden Helix). Analysis was performed using predefined blocks
459 as described within the text and **Supplemental Table S3**. Stepwise regression was performed
460 using backwards elimination and up to 50 EM iterations with a convergence tolerance of 0.0001

461 and frequency threshold of 0.01. Full versus reduced model regression was performed using age-
462 at-diagnosis as a quantitative trait, with race, family history of disease, and menopause status as
463 covariates. Correction for multiple testing was performed using Bonferroni adjusted p values and
464 1,000 full scan permutations.

465 **Haplotype frequency analysis.** EM frequencies representing the 1,456 cases defined in *The Two*
466 *Sister Study* were contrasted against population-specific haplotype frequencies. Population-
467 specific data was gathered from phase III of the 1000 Genomes Project and haplotype frequencies
468 were determined using Haploview software (84).

469 **Variance partition analysis.** Data derived from the TCGA Pancancer Atlas Breast Invasive
470 Carcinoma study (70) was evaluated in the R software environment using the VariancePartition
471 application (85). Expression data consisted of z-score measures relative to normal samples
472 obtained through cbioportal. Expression data was unavailable for *ADADI* and hence this candidate
473 was excluded from the analysis. Age-at-diagnosis was correlated with expression data as
474 previously described.

475 **Pancancer mutation analysis.** To evaluate the impact of mutation type on cancer age-of-onset
476 meta-data representing 9 candidate genes from 30 studies was obtained as described. A total of
477 220 donors were excluded due to cross-study differences in the definition of donor age. Pertinent
478 data included age-at-diagnosis/diagnosis age, gene-specific copy number variants, gene-specific
479 coding variants (missense/truncating). Samples lacking mutation in any of the candidate genes
480 were assembled into a control dataset (N = 7026). Experimental populations were defined on a per
481 gene basis and were classified by mutation type (amplifications, deep deletions, or
482 missense/truncating mutations). Distribution analysis was performed using a two sample Z-test

483 and the equation $Z = (\bar{X}_1 - \bar{X}_2) / \sqrt{\sigma_{\bar{X}_1}^2 + \sigma_{\bar{X}_2}^2}$ where \bar{X}_1 is the mean age-at-diagnosis for the control
484 population, \bar{X}_2 is the mean age-at-diagnosis for the case population, $\sigma_{\bar{X}_1}^2$ is the standard deviation
485 for the control population divided by the square root of the number of data points, and $\sigma_{\bar{X}_2}^2$ is the
486 standard deviation for the case population divided by the square root of the number of data points.
487 Corresponding p values were calculated for each independent test statistic.

488 **ACKNOWLEDGMENTS**

489 We acknowledge the Two Sister Study PI, Clarice R. Weinberg, Susan G. Komen for the Cure
490 (grant FAS703856) and the Intramural Program of the National Institute of Environmental Health
491 Sciences. Fei, Cl, DeRoo, L., Sandler, D.P. and Weinberg, C.R. Fertility drugs and young-onset
492 breast cancer: Results from the Two Sister Study. Journal of the National Cancer Institute 104(13):

Table 1. Summary representation of data in terms of methodology.

Screening method	SNVs	Haplotypes	Haploblocks	CHR Rol	Rol
Haplotype (10 kb)	762	4126	762	ND	ND
10^{-4} filter	415	322	282	64	ND
2-6 SNV windows	417	466	165	33	13*
HTR	417	466	165	33	33
Permuted $p \leq 0.05$	64	14	14	14	14

Table 1. Sequential application of methods and filters defines a short list of candidates which may associate with breast cancer age-of-onset. HTR = Haplotype trend regression; SNVs = single nucleotide variants retained at each stage of analysis; Haplotypes = haplotypes retained at each stage of analysis; Haploblocks = haploblocks retained at each stage of analysis; CHR Rol = chromosomal regions defined by the remaining haploblocks; Rol = regions of interest retained after analysis; * indicates region of interest was evaluated by visual assessment of data representation as opposed to statistical measures. ND = Not determined.

Table 2. Haplotype trend regression comparing discordant sibs.

<i>Candidates</i>		<i>Affected</i>			<i>Unaffected Sibs</i>		
<i>CHR</i>	<i>POS</i>	<i>FM P</i>	<i>Bon.P</i>	<i>PermP</i>	<i>FM P</i>	<i>Bon.P</i>	<i>PermP</i>

13	27545444	7.29E-19	1.23E-03	5.0E-03	2.91E-39	1	1
21	18544139	2.15E-18	3.94E-03	2.5E-02	2.10E-37	1	1

Table 2. Haplotype trend regression underscores significant differences between breast cancer patients and unaffected sibs. Haplotype trend regression was performed using haplotypes as defined in **Table 1**. By way of contrast, regression analysis was performed using age-at-diagnosis as a quantitative trait comparing breast cancer patients to unaffected sibs. CHR = chromosome, POS = position of the first marker, FM P = the p value resulting from full model trend regression, Bon.P = the Bonferroni adjusted p value, and PermP = the permuted p value after 1,000 permutations. The 14 haplotypes all showed a significant association with age-of-onset in breast cancer patients, whereas no significance was observed in discordant sibs. Although not displayed, similar analysis using age-at-diagnosis as a categorical variable yielded similar findings.

Table 3. Correlating gene expression with age-at-diagnosis.

GENE	T	PR(> T)	F-STAT	P	VARIANCE
AGO2	-3.86	1.19E-04	14.93	1.19E-04	1.48%
ARHGEF10	-0.89	3.72E-01	0.7984	3.72E-01	0.08%
CNNM1	0.056	9.56E-01	0.0031	9.56E-01	0.00%
IL2	1.32	1.88E-01	1.733	1.88E-01	0.17%
KIAA1109	-4.41	1.13E-05	19.48	1.13E-05	1.92%
LYPD6B	1.41	1.59E-01	1.99	1.59E-01	0.20%
PPFIBP1	-3.28	1.07E-03	10.77	1.07E-03	1.07%
TP73	-0.55	5.83E-01	0.3013	5.83E-01	0.03%

Table 3. Expression of AGO2, KIAA1109, and PPFIBP1 correlates with age-at diagnosis in breast

cancer patients. Gene expression data was regressed using the VariancePartition R package. The additive effect of AGO2, KIAA1109, and PPFIBP1 expression contributed to 4.47% of the variance in age across the TCGA breast cancer data set.

Table 4. Correlating mutation-type with age-at-diagnosis.

GROUP	AMPLIFICATION					DEEP DELETION					MUTATION				
	Mean	SD	N	Z	P	Mean	SD	N	Z	P	Mean	SD	N	Z	P

Table 4. CNNM1 and LYPD6B exhibit bidirectionality of effect on age-at-diagnosis depending upon mutation type. Two-sample Z testing was applied to compare gene-specific mutation types with the control population. Gene amplifications in CNNM1 and LYPD6B correlated with a lower age-at-diagnosis whereas deletions or truncating mutations correlated with an increased age-at-diagnosis.

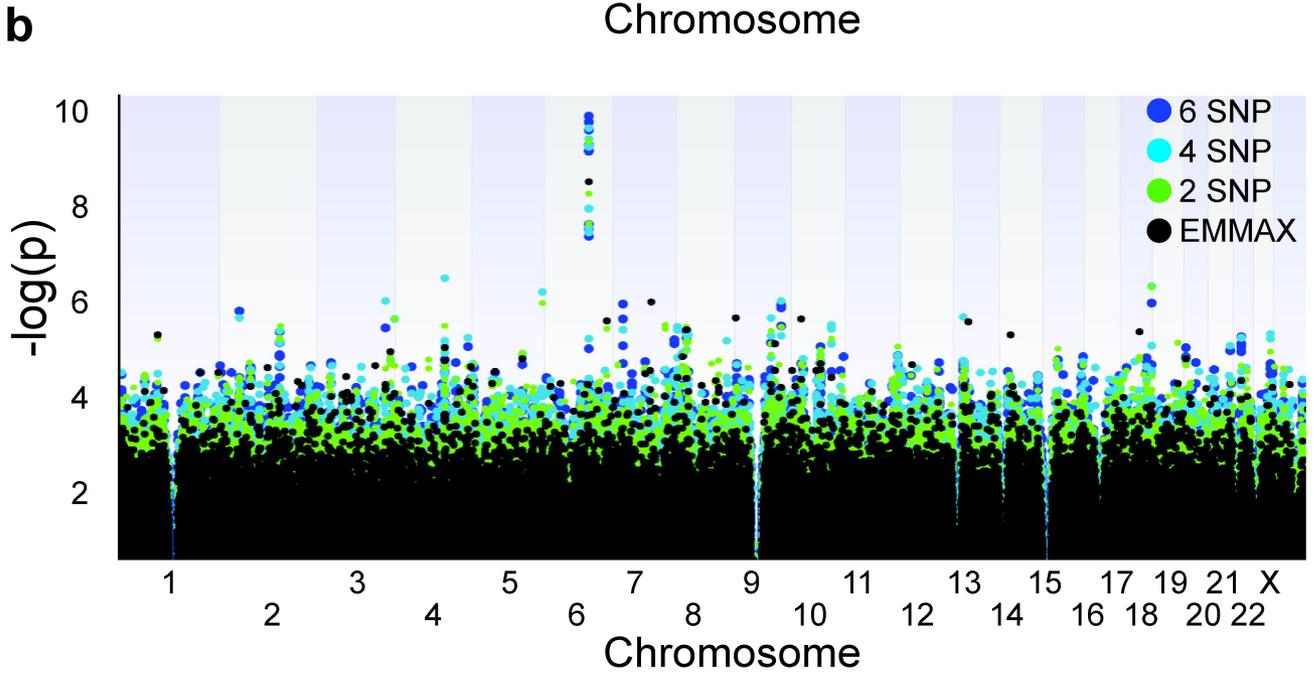

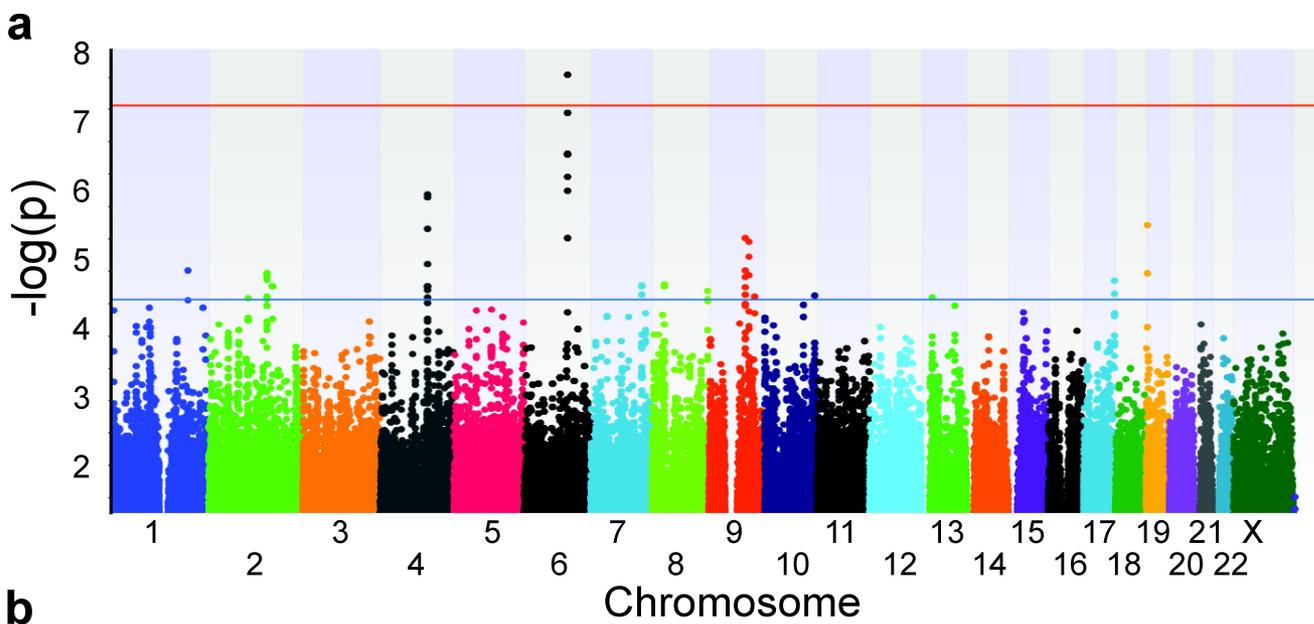

FIGURE LEGENDS

Figure 1. Manhattan plot. Haplotype-based analysis was performed using a fixed window size of 10 kb and an expectation-maximization (EM) algorithm with a maximum of 50 iterations. P values were derived from χ^2 . A Manhattan plot was constructed by plotting $-\log[p]$ against chromosomal position. The horizontal blue line corresponds to a suggestive threshold of $p \leq 5 \times 10^{-5}$. The horizontal red line corresponds to the conventional threshold for genome-wide significance at $p \leq 5 \times 10^{-8}$.

Figure 2. Fine mapping of targeted chromosomal regions. Haplotype analysis was performed using an EM algorithm with a maximum of 50 iterations and sliding windows consisting of 2-6 SNPs. Haplotype windows were aligned and graphically depicted using the GrASP excel macro. Individual haploblocks are color-coded to represent p values (dark green $p > 5 \times 10^{-5}$; light green $p \leq 5 \times 10^{-5}$; yellow $p \leq 5 \times 10^{-6}$; orange $p \leq 5 \times 10^{-7}$; red $p \leq 5 \times 10^{-8}$).

Figure 3. Odds ratios associated with candidate haplotypes. EM frequencies were used to calculate odds ratios and 95% confidence intervals comparing frequencies between younger and older populations within *The Two Sister Study*.

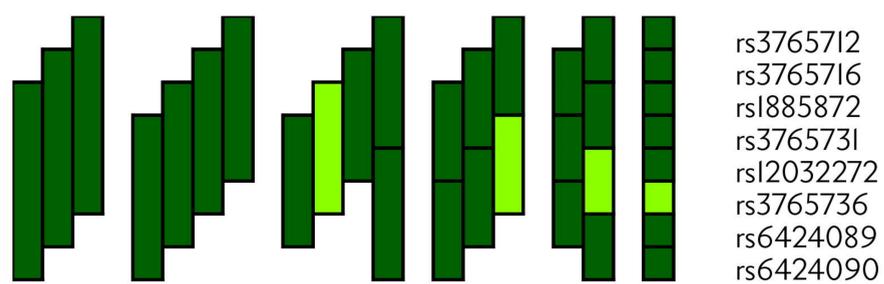

Figure 4. Comparison of haplotype frequencies in The Two Sister Study and phase III of the 1000 Genomes Project. Bar graphs present the ratios formed by dividing *The Two Sister Study* haplotype frequency with population-specific haplotype frequencies obtained through the 1000 Genomes Project. AFR = African, AMR = American, EAS = East Asian, EUR = non-Finnish European.
