Abstract

Acute myocardial infarction (AMI) is a leading cause of mortality and morbidity worldwide. Using a validated and efficient ICP-MS/MS-based workflow, a total of 30 metallomic features were profiled in a study comprising 101 AMI patients and 66 age-matched healthy controls. The metallomic features include 12 essential elements (Ca, Co, Cu, Fe, K, Mg, Mn, Na, P, S, Se, Zn), 8 non-essential/toxic elements (Al, As, Ba, Cd, Cr, Ni, Rb, Sr, U, V), and 10 clinically relevant element-pair product/ratios (Ca/Mg, Ca×P, Cu/Se, Cu/Zn, Fe/Cu, P/Mg, Na/K, Zn/Se). Preliminary linear regression with feature selection confirmed smoking status as a predominant determinant for the non-essential/toxic elements, and revealed potential routes of action. Univariate assessments with adjustments for covariates revealed insights into the ambivalent relationships of Cu, Fe, and P with AMI, while also confirming cardioprotective associations of Se. Also, beyond their roles as risk factors, Cu and Se may be involved in the response mechanism in AMI onset/intervention, as demonstrated via longitudinal data analysis with 2 additional time-points (1-/6-month follow-up). Finally, based on both univariate tests and multivariate classification modelling, potentially more sensitive markers measured as element-pair ratios were identified (e.g., Cu/Se, Fe/Cu). Overall, metallomics-based biomarkers may have utility for AMI prediction.

Keywords

Metallomics, Ionomics, Acute Myocardial Infarction, Coronary Heart Disease, Cardiovascular Disease, Copper, Selenium, Biomarker, ICP-MS

1. Introduction

Acute myocardial infarction (AMI), a condition classified under coronary heart disease (CHD), is one of the leading causes of mortality and morbidity worldwide despite remarkable progress in disease diagnosis and treatment.^{1, 2} Both clinical and epidemiological studies have demonstrated the cardioprotective and detrimental associations of essential minerals and non-essential/toxic metal exposure respectively, with risks of AMI, CHD, or cardiovascular disease (CVD) in general.^{3, 4} However, given the global-acting and non-independent nature of these various metals in health and disease, their values as biomarkers are limited. Moreover, the benefits of public health efforts and intervention strategies (*e.g.*, via dietary supplementation or reducing anthropogenic exposure) remain unclarified.^{3, 4} Thus, more accurate and in-depth characterisation of the associations between these different types of elements with AMI aetiology is vital.

Thus, omics strategies such as metallomics have great merit, as the interplay between various non-independent elements and other biomolecules may be revealed. However, as shown in a recent bibliometric analysis on omics applications in CHD research, comprehensive metallomics analysis has seldom been done in this area, and there was only 1 study on blood plasma metallomics study in a subgroup of AMI patients.⁵ This could be because metals have rarely been conjugated with the omics world unlike the other omics frontrunners, and that metallomics only garnered greater attention recently.^{5, 6} Nevertheless, metallomics has already been widely applied in environmental studies and toxicological appraisals, and methods have been rapidly developed to enable quick and efficient metallomic profiling.⁷ This study's overarching goal is therefore to capitalise on such developments for bridging existing research gaps regarding the AMI metallome.

With that overarching goal, our study aims to assess both essential elements and non-essential/toxic elements with as wide a coverage as possible. To achieve that, the inductively

coupled plasma – mass spectrometry (ICP-MS) with MS/MS and collision/reaction cell (CRC) capabilities was used for its remarkable sensitivity, enabling the analysis of more elements at trace and ultra-trace levels.⁸ Also, beyond solely comparing elemental concentrations in the blood plasma, element ratios are also relevant. This is because the dynamic balance or metabolic crossroads of multiple elements have implications on various biological processes in human health and disease, and could also potentially link health/disease with diet and environmental changes.⁹ Thus, we identified a few element-pairs relevant to CVD and in human health in general: Ca/Mg^{10, 11}, Ca×P¹²⁻¹⁴, Cu/Se¹⁵, Cu/Zn^{16, 17}, Fe/Cu¹⁸, Na/K^{19, 20}, P/Mg²¹, and Zn/Se¹⁵. Our work thereby includes these additional variables as part of the metallomics profile, to paint a more comprehensive picture about these elements in AMI.

In summary, because few studies have examined the association between circulating element (both essential and non-essential/toxic) levels and AMI, and none so far has also comprehensively assessed several element product/ratios in Asian populations across 3 time-points, our study presents useful insights into the pertinent disturbances in AMI metallome.

2. Materials and methods

2.1. Reagents and chemicals

All chemicals used were of trace analysis grade (99.999%) unless otherwise stated, and ultrapure water was also used for all chemical and sample preparation. The multi-element standard (IV-ICPMS-71A) was purchased from Inorganic Ventures (Christiansburg, VA, USA), and it contains the following elements in 3% nitric acid: Ag, Al, As, B, Ba, Be, Ca, Cd, Ce, Co, Cr, Cs, Cu, Dy, Er, Eu, Fe, Ga, Gd, Ho, K, La, Lu, Mg, Mn, Na, Nd, Ni, P, Pb, Pr, Rb, S, Se, Sm, Sr, Th, Ti, Tm, U, V, Yb, Zn. The ICPMS internal standard mix was purchased from Agilent Technologies (Santa Clara, CA, USA, and it contains Bi, Ge, In, Li-6, Rh, Sc and Tb. The 60% nitric acid (ultrapure; any metals at sub ppt levels) used for all experiments was purchased from Kanto Chemical Co. (Tokyo, Japan).

2.2. *Patients and controls*

This study was approved by the National Healthcare Group Domain Specific Review Board (NHG DSRB; REF NO. 2013-00248 and 2016-00210), and all subjects gave their informed consent to participate prior to the inclusion. All experiments were performed in compliance with the relevant laws and institutional guidelines. Blood plasma samples from 101 AMI patients were collected from the National University Heart Centre, Tan Tock Seng Hospital, Changi General Hospital, Sarawak General Hospital Heart Centre, and Christchurch District Hospital. AMI plasma samples were collected 24-48 hours post-percutaneous coronary intervention (PCI). Samples from two additional follow-up time-points were also collected from the AMI patients (T1: 24 – 48 hours post-PCI; T2: 1 month after T1; T3: 6 months after T1). Blood plasma samples from 66 matched healthy community-dwelling controls were collected from Singapore. All blood samples were immediately centrifuged at – 4 °C and were stored at – 80 °C prior to analysis.

2.3. *Metallomics sample preparation*

To obtain elemental samples from human blood plasma, acid digestion aided with heating via a hotplate was done. Specifically, 80 µL blood plasma was added into a 15 mL polypropylene centrifuge tube, followed by the addition of 80 µL ultrapure water and 80 µL ultrapure nitric acid. The centrifuge tubes were gently swirled to allow mixing. Immediately after, the samples were heated using a hotplate at 98 °C for 2 hours. To further process the samples for ICP-MS analysis, the digested samples were diluted to 8 mL with ultrapure water. The diluted samples were then filtered using 2.2 µm PTFE syringe filters into clean centrifuge tubes. Blank samples were prepared in the same way, but with the blood plasma component replaced with ultrapure water. The samples were then stored at 4 °C until ICP-MS analysis as recommended by a recent report.²²

2.4. *ICP-MS analysis*

ICP-MS analysis was done using the 8900 ICP-MS/MS system (equipped with triple quadruple mass spectrometer) from Agilent Technologies. To optimise sensitivity and accuracy, various CRC modes using the tandem mass spectrometer were used to quantitate different elements. Supplementary Table S1 summarises the instrument and CRC parameters. To correct for matrix effects and non-spectral interferences, multiple elements from the internal standard mix were spiked online and elemental concentrations were normalised to the internal standards. To obtain optimal precision and accuracy, the internal standard analyte for each element was selected as close in mass number as possible to that of the analyte element, with ionisation energies considered as well. The masses and mass shifts used for integration for each element and the corresponding internal standard analytes are included in Supplementary Table S2. To obtain elemental concentrations of the samples, external standard calibration was done using the multi-element standard prepared in various concentrations. It was noted that a few elements (Al, Ca, K, Mg, Na, P, S) were present in higher abundance where their concentrations in some or all of the plasma samples exceeds the external standard calibration range. To determine their concentrations, the samples were diluted (dilution factor = 50) and re-analysed by the ICP-MS.

2.5. Data processing and statistical analysis

All statistical analyses were conducted in *R* (R Core Team).²³ Normality of all metabolite and glycan features was first assessed via the Kolmorov-Smirnov test. Since non-normal distributions ($p < 0.05$ based on Kolmorov-Smirnov test) were found with some of the features, non-parametric tests were done subsequently. Baseline characteristics among patients and controls were compared using Mann Whitney test for continuous variables, and Fisher's Exact test for categorical variables. Differences in plasma levels of the metallomic features between patient groups were also assessed using the Mann Whitney test. Linear regression modelling for identifying independent determinants of the metallomic features amongst covariables was

done with backwards elimination to remove non-significant variables until all variables remaining in the model had p -value < 0.05 . Analysis of covariance (ANCOVA) with the inclusion of significant determinants as covariates was done by implementing a generalised linear model (GLM) with Bonferroni correction for multiple comparisons. Analysis of the longitudinal data with 3 time-points was achieved via Friedman test, and Kendall's W coefficient of concordance was evaluated as the effect size for Friedman test.

Classification modelling was done on MetaboAnalyst (<http://www.metaboanalyst.ca>). To prepare the dataset with both clinical and metallomics variables for multivariate analysis, log-transformation and scaling via mean-centring was done. The receiving operating characteristic (ROC) curve for biomarker identification and performance evaluation was generated based on random forest classification modelling with repeated random sub-sampling cross-validation (30 iterations; each iteration uses 2/3 samples for feature selection and model training, and remaining 1/3 for testing). Important features were identified and ranked based on decreases in accuracy.

3. Results and discussion

3.1. Generation of plasma metallomic profiles

Out of 43 elements from the multi-element standard, 22 were successfully quantified from the human blood plasma samples via ICP-MS analysis as described. To validate that the sample preparation workflow involving nitric acid digestion with hotplate-assisted heating was sufficient to digest and stabilise the 22 detected elements, and that the CRC modes and internal standard elements were appropriate, method repeatability and recovery were assessed.

For assessing intra-day repeatability/precision, three independent digestions of the same pooled plasma sample spiked with multi-element standard (final concentration of each element = 500 ppb) were done and analysed. Additional tests with dilution (dilution factor = 50) were

also done for evaluating some of the elements present at lower amounts in blood plasma. For assessing inter-day repeatability or intermediate precision, nine independent extractions from the same pooled plasma sample were prepared over three days. All replicates were analysed using the ICP-MS using the same operating conditions. RSD values (both intra- and inter-day) for all 22 elements were low (range: 1.3 – 7.9 %), demonstrating satisfactory method repeatability/precision. The RSD values are deemed satisfactory by cross-checking with recent publications on ICP-QQQ-based metallomics methods.^{24, 25} Next, to assess recovery, element concentrations obtained from samples spiked with multi-element standard before and after digestion were compared. All 22 elements have recoveries roughly within +/- 10 % threshold from 100 % (range: 89.9 – 105.2 %). This indicates satisfactory recovery of the entire analytical workflow. Additionally, it was also confirmed in this study that all elements analysed have baseline equivalent concentrations lower than their quantified concentrations in the pooled plasma sample, and that the calibration curves have R^2 values > 0.9995 which demonstrates good linearity.

However, we note that there were also some biologically relevant elements not quantifiable using our analytical workflow. Prominent examples include mercury as well as halogens like iodine, where additional steps and reagents may be required to counter issues with stability, memory effects, etc.^{26, 27} Nonetheless, together with the satisfactory precision, recovery, and good analyte coverage of 22 elements, this metallomics workflow without the need for microwave digestion was simple and efficient. Thus, we applied it on the plasma samples of AMI patients and healthy controls to generate their metallomic profiles first consisting of elemental concentration data. Relevant element-pair product/ratios were also calculated. The 12 essential elements studied here are Ca, Co, Cu, Fe, K, Mg, Mn, Na, P, S, Se, and Zn. The 10 non-essential or toxic elements are Al, As, Ba, Cd, Cr, Ni, Rb, Sr, U, V. As a whole,

metallomic profiles comprising both elemental concentrations and element-pair product or ratios (30 metallomic features in total) were generated for each sample.

3.2. Baseline characteristics and their associations with the metallome

The baseline characteristics (including demographic characteristics, medical history related to the disease, as well as traditional cardiovascular risk factors and predictors of AMI and adverse events) of the study populations are summarised in Table 1. As the healthy controls were age-matched to the AMI cases, there are no statistically significant differences ($p > 0.05$) in age distributions between the AMI and healthy groups. However, the distributions of gender, smoking status, and race were found to be significantly different between the two groups ($p < 0.0001$). Next, for the medical history (Table 1), they are closely matched between AMI and control groups, with the only exception being dyslipidemia ($p < 0.001$). For variables such as troponin T as measured via the high-sensitivity test (hsTnT) and N-terminal-pro hormone brain natriuretic peptides (NTproBNP), the highly significant differences are expected as they are biomarkers of AMI, and positive troponin was also an inclusion criterion for the AMI cases. As for other traditional cardiovascular risk factors, several of them (diastolic blood pressure (DBP), systolic blood pressure (SBP), high-density lipoprotein-cholesterol (HDL-C), white blood cell count (WBC), and creatinine levels are also statistically significant variables ($p < 0.0001$).

We note that the above variables could be possible confounders in this metallomics study. As such, before comparing the metallomic profiles between the AMI and healthy groups, we determined whether the aforementioned demographic characteristics and traditional CVD risk factors were independent determinants of plasma levels of the metallomic features. For that purpose, we fitted a linear model with each metallomics feature as the dependent variable and the demographic characteristics and traditional CVD risk biomarkers as independent variables.

Backwards elimination was performed to remove non-significant independent variables until all variables remaining in the model had p -values < 0.05 . The β coefficients and significance levels of the determinants are summarised in Table 2. The determinants identified for each metallomic feature would then be included as covariates for ANCOVA when assessing statistical differences between AMI versus healthy in the next section.

Regardless, with reference to Table 2, various noteworthy associations of metallomic features with demographic characteristics and cardiovascular risk factors were identified. Firstly, smoking status is associated with the greatest number of metallomic features, and predominantly in the non-essential or toxic elements (*i.e.*, Al, Cd, Rb, Sr, U, V; all $p < 0.01$). This could be expected as several of these elements are found in tobacco, cigarette paper, filters, and cigarette smoke (except U).^{28, 29} It has also been revealed that the levels of these elements in circulation are affected by smoking, and they are linked to the disturbance of metal homeostasis and the pathogenesis of diseases.^{28, 29} Moreover, out of the essential elements, Zn was also negatively associated with current smokers. This decrease could either be attributed to the link between Zn and nicotinic receptors stimulation (lower Zn levels = cause/predisposition of smoking),³⁰ or attributed to increased blood Cd concentration which induces expression of metallothionein binding of both Cd and Zn (lower Zn levels = effect of smoking).^{28, 31} This is particularly relevant to our study on AMI as smoking-induced lowered Zn levels may lead to cellular ageing (oxidative stress) and increases the risk of hypertension.³²

Secondly, three other pertinent metal-cardiovascular risk factor associations are (1) increasing Cu with lowering of cholesterol and increase in LDL-C, (2) increasing As with lowering of white blood cell levels, and (3) increasing Cu/Zn ratio with increasing creatinine (all $p < 0.01$). For Cu, it has been reported that Cu deficiency is associated with increased total cholesterol.³³ While the direction of association in our study matches for total cholesterol levels, it was the opposite for LDL-C. Nevertheless, this could imply that an increased LDL-C

may not be a true artefact of Cu deficiency, but it could be oxidised LDL instead. This observation could be specific to our study on AMI patients, and the postulation could possibly be explained by Cu's promotion of LDL-C oxidation.^{34, 35} Next, for As, its negative association with white blood cell levels could be expected as various reports have revealed that arsenicosis or As exposure is associated with the prevalence of leukopenia³⁶ since As drives apoptosis in human lymphocytes via mechanisms related to oxidative stress, cytokine production, etc.³⁷ This is of relevance as an elevated WBC count has been directly associated with CHD and CVD adverse events in the African-American and White populations.³⁸ Thus, while As's toxicity makes high As levels undesirable, it could also be possible to observe higher levels of As in healthy people than AMI patients due to As's control of WBC counts. Finally, for the positive association of Cu/Zn ratio with creatinine, it serves to highlight the possible complications with renal issues since creatinine is an indicator of kidney malfunctions. Lower Zn has also previously been found in patients with end-stage renal disease while creatinine was shown to be a determinant of plasma Cu levels, augmenting our hypothesis.³⁹

3.3. Statistical comparisons of metallomic profiles between AMI and healthy, and across 3 time-points

Mann Whitney test was first employed to identify metallomic features which are significantly different in AMI patients. Table 3 summarises their distributions, the *p*-values, as well as the direction of change in terms of the composition in AMI patients (measured at T1: 24 – 48 hours post-PCI) compared to the healthy. To reduce bias and assess for the possible attenuating influence of the determinants on each metallomic feature, adjusted *p*-values from ANCOVA were also obtained and are provided in Table 3. To augment conjectures made regarding co-acting elements, Spearman correlation analysis between element levels was also done and results are summarised in a correlation heatmap (Figure 1). For the significantly altered metallomic features, further assessment on their changes across 3 time-points was also

done to determine if their dysregulation persists after 1 and 6 months (T2, and T3 respectively). For that purpose, Friedman test (non-parametric version of repeated-measures ANOVA) was applied to the longitudinal data to test for any significant changes (Table 4). Violin plots were also generated to visualise their trajectories (Figure 2). It is noted here that the simpler repeated measures test was used instead of more popular and robust options like the generalised linear mixed-effects model or the growth curve model based on characteristics of our data: (1) small number of time-points which we will assess as discrete time-points, (2) complete and no missing data, (3) simple design, comparison across time-points without assessing additional between/within-subjects factors.

3.3.1. Ambivalent relationships of essential element levels with AMI

As a whole, out of the 12 essential elements assessed using the Mann Whitney test, the AMI patients had significantly elevated Cu, Mg, and Na levels in their blood plasma as compared to the healthy controls, while Fe, P, and Se were decreased in levels (all $p < 0.05$; Table 3). However, the p -value for Mg was attenuated to a non-significant level when ANCOVA was done. We therefore also exclude Mg as a significant variable for AMI risk. For the rest of the essential elements, significant differences in distributions are expected. Also, out of these essential elements, Cu and Se levels were significantly different at the different time-points ($p < 0.0001$ and 0.05 respectively; Table 4), although detected effect sizes were considered small (0.10 and 0.04 respectively). The possible trajectory of hsTnT, a more specific and choicer biomarker of AMI, is included in Figure 4 for comparison purposes. Since troponin T are released because of cardiac injury and myocardial necrosis (*i.e.*, consequence of AMI instead of cause), their serum levels peak 24-48 hours and return to baseline over 10-14 days.⁴⁰ Their trajectory of drastic decrease at T2 and T3 as shown in Figure 4 is thus expected. By extension, we expect that specific markers elevated/decreased due to AMI onset or progression could show observable trajectories as well. Thus, we determined that Cu and Se could be more

specific markers associated with the defence/response mechanism in AMI, on top of their roles in increasing general cardiovascular risk. On the other hand, significantly altered essential elements in AMI patients that did not have their levels returned closer to levels in healthy subjects after 6 months (T3) could be less specific risk factors. This applies to Mg, Na, Fe, and P. More experiments testing the levels of Cu and Se immediately after hospitalisation due to chest pain, and before/after surgical intervention may be required to understand their changes better. We discuss each significantly altered essential element in the following paragraphs in greater detail.

Firstly, for Na, the observed elevated Na levels in AMI patients ($p < 0.05$) is consistent with the literature, with the predominant view being that Na is a risk factor of CHD through increasing blood pressure and causing hypertension.⁴¹ Secondly, we observed lower Se levels in AMI patients ($p < 0.01$), which is also consistent with various meta-analyses on CVD and CHD.⁴²⁻⁴⁴ Available evidence indicates that the role of Se in human health and CVD is mostly attributed to its presence in antioxidant and redox-relevant selenoproteins, *e.g.*, glutathione peroxidase, thioredoxin reductase.⁴⁵ Despite that, supplementation trials did not find any significant protective effect of Se supplementation on CVD and adverse outcomes including AMI.⁴⁵ Meanwhile, the non-significant linear association between Se and the lipid profile variables found in this work also supported such studies reporting that Se supplementation does not have effects on an aberrant lipid profile.⁴⁶ Our work also suggests that the previous link between Se and aberrant lipid profiles could also be associated with Se's link with Cu instead. The AMI Cu/Se levels and significant difference ($p < 0.0001$) observed in this work is firstly in line with a previous report¹⁵, and secondly also showed linear associations for cholesterol and LDL-C. Additionally, with reference to Table 4, we observed a significant increase in Se levels from a median of 90.31 to 94.11 ng/mL in AMI patients at T2, which remained consistent at T3. However, Se concentration at T3 (median = 94.50 ng/mL) is still significantly lower than

in healthy patients (median 99.98 ng/mL; $p < 0.05$). Thus, we postulate that the lower Se levels at T1 could be related to the cardiac surgery (PCI), which may have served as an ischemic stimulus that activated inflammatory responses, thereby aggravating the decrease of circulating Se intra/-post-operation.^{47, 48}

Besides Se and Na, the other significantly altered essential elements (Cu, Fe, and P) seemed to contradict the predominant views based on earlier research in cardiovascular health. In contrast, our results augment the standpoint that essential elements should have ambivalent associations with disease risk via a U- or J-shaped trend. This U/J-shaped trend is commonly associated with the dose-response relationship concept in toxicology, but it also applies to essential substances such as vitamins as well as essential trace elements.⁴⁹ While overload/overexposure of these elements may be toxic and incur health issues, the deficiency of these essential elements may also cause adverse effects.⁴⁹ Our results may suggest a need to redefine the normal range for these essential elements, and that the predictive value of these circulating element levels for AMI may be improved by accounting for the U/J-shaped trend.

Firstly, for Cu, Cu depletion/deficiency was more commonly reported as a risk factor of the CVDs and even a leading cause of CHD particularly.⁵⁰⁻⁵² Cu plays essential roles in many biological processes (*e.g.*, co-factor for many antioxidant enzymes, involvement in glycation, possible involvement in cytochrome and mitochondria activity, regulation of blood vessels' response to inflammatory stimuli), and its deficiency could dysregulate these processes, leading to the promotion of disease.^{50, 51} However, there has also been contradicting reports on elevated circulating Cu found in CHD patients in large-scale studies from the USA and Finland, as well as in a smaller study in Iran.⁵³⁻⁵⁶ The results from our study agree with these reports (Table 3). Interestingly, when comparing between these studies as well as present work, it seemed that the elevated Cu was consistently seen in both prospective and cross-sectional studies.⁵³⁻⁵⁶ This

indicates that Cu concentrations were elevated in CHD patients when measured both before and after atherosclerotic events. This allows us to conclude that elevated circulating Cu is likely a causal/risk factor. Nevertheless, we cannot exclude the possibility that elevated Cu is also a consequence of atherosclerotic events, as a previous study monitoring serum Cu concentrations of AMI patients over 14 days after infarct reported that serum Cu levels gradually attained peak value on the 7th day after an initial rise on day 1 without returning to normal levels after 2 weeks.⁵⁷ With reference to Table 4 and Figure 2, our study also showed that Cu levels remained elevated in AMI patients at T1 (24-48 hours after PCI) and T2 (1-month after T1), but significantly falls during the 6-month follow-up ($p < 0.0001$). While the effect size was small ($W = 0.10$), the result still demonstrates that the observed rise in Cu could be in part a specific defence mechanism in response to myocardial damage.⁵⁷ Thus, we conclude that Cu could be associated with AMI as both a cause and a consequence.

Secondly, for Fe, it was reported that the conventional iron hypothesis supported by various studies was first proposed by Sullivan, that iron depletion protects against CHD.⁵⁸ Though there were also reports with contradicting conclusions. However, it was more recently recognised that both Fe overload and deficiency are associated with increased cardiovascular morbidity and mortality.⁵⁹ In the Ludwigshafen Risk and Cardiovascular Healthy (LURIC) study, a J-shaped association of Fe load was observed and proposed.⁶⁰ Our work, showing lower Fe levels in AMI ($p < 0.01$), adds to the overall discussion regarding this ambivalent relationship between Fe and disease. Additionally, despite both Cu and Fe possibly having ambivalent relationships with AMI, such ambivalence does not necessarily mask the association of Fe/Cu ratio with AMI. In contrast, our results showed that Fe/Cu may be a more sensitive risk marker than either Cu or Fe alone ($p < 0.0001$; Table 3). However, while numerous Fe-Cu interactions were uncovered over recent years, it is unclear how the CVDs

and AMI are affected. Nevertheless, the potential of Fe/Cu ratio as a sensitive marker is further revealed via multivariate analysis and classification modelling in *section 3.4* below.

Finally, for P, high phosphate levels (*i.e.*, hyperphosphatemia) has been consistently linked with cardiac calcification, left ventricular hypertrophy, and cardiovascular events and death, regardless of comorbidity with chronic kidney disease (CKD).⁶¹⁻⁶³ Concerning AMI in particular, the pro-atherogenic mechanism and formation of atherosclerotic plaques caused by phosphate excess is still unclarified and controversial.⁶³ However, instead of being cardio-protective, our work shows that P levels are significantly lower in AMI patients as compared to the healthy controls ($p < 0.05$; Table 3). Our observations validate the findings by Hayward et al., who reportedly was the first to identify that low P level is also a risk factor for heart disease in adults in a large-scale UK-wide retrospective cohort study.⁶⁴ Next, an approach using Mg supplementation had been introduced to target hyperphosphatemia-associated cardiovascular risk in CKD patients by Sakaguchi and coworkers.^{21, 65} As such, to indirectly investigate the possible balance between Mg and P with AMI and whether increased Mg levels is linked with lowered hyperphosphatemia-linked AMI, we compared the P/Mg ratios. However, our study showed that AMI patients have a significantly lower P/Mg ratio than the healthy ($p < 0.001$; Table 3). This contradicts previous findings by Sakaguchi and coworkers, suggesting that the high P and low Mg correlation could be specific to CKD patients. We thus suggest that further large-scale studies perform subgroup analysis of AMI patients with and without CKD when assessing the P and Mg relationship. A more nuanced approach is also needed when considering Mg supplementation for reducing cardiovascular mortality in CKD patients, or vice versa. Finally, besides Mg, Ca has also been linked with P, and a deranged Ca-P metabolism was identified as a major non-traditional cardiovascular risk factor for both CKD patients and even among individuals with intact renal function.^{66, 67} The link between Ca and P is multi-pronged, including Ca's involvement in the metabolic regulation of phosphate, high

phosphate contribution to vascular calcification, and valve calcification via pathological and concurrent depositions of Ca-P salts on cardiac valves.^{63, 68} However, in the current study, there is no significant association of circulating Ca levels with AMI cases ($p > 0.05$; Table 3), and we saw no significant difference in Ca×P products between groups after adjustments for covariates. This is contrary to previous results regarding coronary artery calcification and coronary heart disease risk.^{13, 14} Thus, while our study shows that Ca and P levels are indeed correlated (Figure 1), we can only conclude Ca's involvement in phosphate metabolism (or vice versa). On the other hand, the utility of the Ca×P product as a CVD or AMI biomarker is limited and requires re-assessment.

3.3.2. *Non-essential or toxic elements, except As, are not specifically associated with AMI*

Through the Mann Whitney test, Al, Ba, Rb, and Sr were found to be significantly elevated in AMI patients, while As levels were lowered. However, for most of them (Al, Rb, and St), their p -values were attenuated to non-significance upon ANCOVA. This was expected, as smoking status is a confounder for the various elements (discussed in more detail in section 3.2). Based on our findings, we suggest future studies definitively include smoking as a covariate for these elements to avoid inflating their roles in diseases.

Next, as for Ba, its levels were significantly higher (adjusted $p < 0.05$) in AMI patients. Ba has been seldom associated with AMI, and the few epidemiological studies assessing its link to the CVDs (especially from drinking water) did not reveal Ba as a risk factor of clinical significance.⁶⁹⁻⁷¹ The reported cardiovascular effects by Ba include adverse effects on heart rhythm and hypotension, which were suggested to be caused by Ba-induced hypokalemia.⁷² However, correlation analysis did not reveal significant linear associations between Ba and K in our study populations (Figure 1). Moreover, the p -value from the univariate comparison between AMI and healthy was attenuated close to borderline significance after adjustments for race and white blood cell levels. Thus, since our study lack information regarding the level of

exposure to Ba through any possible routes (*e.g.*, drinking water or clinical sources like Ba contrast solution used in radiologic examinations), we could not make further assessments regarding the specific role of Ba in AMI. Regardless, Ba remains to be of limited significance as a risk factor for AMI.

For As, unexpectedly, we found lower As levels in AMI patients than healthy, which *p*-value remained significant after ANCOVA ($p < 0.001$). There is ample evidence that CHD risk is positively associated with inorganic As exposure (via drinking water, rice, etc).⁷³⁻⁷⁶ Other than the use of As trioxide as a chemotherapeutic or antineoplastic drug, As does not have any known benefits to human health.⁷⁷ Since history of malignancy within the last 12-months was an exclusion criterion for the study's sampling design, we may exclude As bioaccumulation from such exposures as a possible explanation. Alternatively, the lowered As could be an indirect response to effects induced by the PCI. This is supported by our observation that As levels at T2 and T3 were significantly increased from T1 based on the repeated measures ANOVA and post-hoc pairwise comparisons ($p < 0.0001$), and that levels at T3 were not significantly different from healthy based on a Mann Whitney test ($p > 0.05$). Further studies on As metabolism in AMI onset/intervention strategies are needed to evaluate this possibility. Regardless, the non-significant difference between As levels in AMI patients and T3 versus in healthy subjects could be attributed to the biospecimen being studied. While chronic low As exposure may result in As accumulation in blood, there are notable differences between the profiles of As species in the plasma and the urine, and these different species could be indicators of sources of As (organic forms from dietary sources, or inorganic forms from environmental exposure).⁷⁸ Additionally, methylated forms of As have been suggested as indicators of effective biotransformation/detoxification of the inorganic As species. Other organic species such as As-betaine, which are principally introduced from seafood and agricultural products, also has low toxicity despite being found in human serum.⁷⁹ Finally,

previous work also reported different As speciation profiles in different cardiovascular tissues of CHD patients.⁸⁰ Thus, we recommend future work to perform As speciation analysis instead of mere total As measurements in circulation, to more accurately define the contribution of As in AMI.

3.4. Classification modelling and performance of metallomics as AMI biomarker

Notwithstanding the possible diverse roles of the various elements as either non-specific and non-independent risk factors or as more specific markers related to cardiac injury and surgery, we performed classification modelling using all metallomic features to assess the performance of metallomics as a biomarker. Age and the traditional cardiovascular risk factors measured in routine tests (DBP, SBP, triglyceride, cholesterol, HDL-C, LDL-C, WBC, platelet, creatinine) were also included in the modelling for comparison purposes. A total of 40 variables (30 metallomic features + 10 clinical variables) was explored. The ROC curves based on models formed with varying numbers of features were generated, and predictive accuracies were also calculated as an average based on 30 iterations (Figure 3).

As reflected in Figures 3A and 3B, the best performing model with an area under curve (AUC) of 0.942 (95% CI 0.889 - 0.970) and predictive accuracy of 87% was made up of a combination of 10 variables. The top 10 important features selected for the random forest classifier are thus also shown in Figure 3A. While the top 3 variables are clinical variables (WBC, HDL-C, and cholesterol), the following variables are all metallomic features (Fe/Cu, Ca/Mg, Fe, P/Mg, Zn, As, Se). This suggests the potential of metallomic features for the replacement or concurrent usage with current risk factors in predicting AMI.

Next, the identification of Fe/Cu ratio as an important variable augmented the univariate results in suggesting it as a potentially more sensitive biomarker for AMI than the 2 metals individually. Also, the inclusion of Cu, Se, and As as important features may also confer

specificity of the model for AMI prediction or prognosis, based on postulations regarding their changes at T2 and T3 as discussed earlier. However, out of the important variables, Ca/Mg and Zn were not found to be significantly altered in AMI based on univariate comparisons. In line with random forest classifiers' non-linear nature, our results suggest that Ca/Mg and Zn's relationships with AMI, at least in the populations studied, could be non-linear.

4. Conclusions

In summary, a total of 30 metallomic features (12 essential elements, 10 non-essential or toxic elements, as well as 8 element-pair product/ratios) were profiled via a validated and efficient ICP-MS/MS-based workflow. Greater insights into the mechanisms and ambivalent relationships of the essential elements (*e.g.*, Cu, Fe, and P) with health and disease were revealed based on our results and comparisons with literature. Additionally, changes in the AMI metallomic profile across 3 time-points revealed possible roles of Fe, Na, and P as stable but non-specific risk factors of AMI, and Cu and Se as more specific biomarkers. Based on the analysis of product/ratios calculated from related essential element pairs, more sensitive variables are identified (*e.g.*, Cu/Se, Fe/Cu). Classification modelling also revealed several metallomic features as potential biomarkers that may be used in replacement of or alongside traditional cardiovascular risk factors for AMI prediction.

Finally, our study has some limitations. Firstly, the sample size was relatively small, and the proposed U/J-shaped trend for the essential elements' ambivalent associations could not be tangibly visualised. Secondly, while the longitudinal analysis across 3 time-points provided intriguing hypotheses on element concentrations' causal/consequential links to AMI, further studies over longer periods and also specifically on closer time-points before and after intervention are required to confirm the hypotheses. Speciation analysis, especially for elements such as Se and As, are also recommended to better understand their modes of action in AMI for more specific therapeutic strategies and biomarker development.

1 **Table 1.** Baseline characteristics of the study populations.

Characteristic	AMI (n=101)	Control (n=66)	p-value ^a
<i>Demographic variables</i>			
Age (Median [Min-Max])	57 (33 - 81)	54.5 (40 - 71)	2.66E-01
Gender (Female) (%)	12.9	40.9	<u>6.30E-04</u>
Smoker (%)			
Non	37.6	90.9	
Current	35.6	3.0	
Ex	26.7	6.1	
Race (%)			<u>1.00E-14</u>
Chinese	27.7	60.6	
Malay	21.8	9.1	
Indian	6.9	30.3	
Others	43.6	0.0	
<i>Cardiovascular risk factors based on medical history</i>			
Prior MI (%)	4.0	0.0	1.54E-01
FH of CHD (%)	20.8	10.6	9.40E-02
Diabetes (%)	20.8	12.1	2.10E-01
Hypertension (%)	43.6	28.8	7.20E-02
Dyslipidemia (%)	42.6	77.3	<u>3.30E-05</u>
<i>Other cardiovascular risk factors, predictors of AMI and adverse events (Median [Min-Max])</i>			
DBP, mm Hg	83.50 (39 - 138)	74 (53 - 107)	<u>1.65E-04</u>
SBP, mm Hg	140 (74 - 241)	127 (97 - 175)	<u>8.22E-06</u>
Triglyceride, mmol/L	1.50 (0.35 - 5.58)	1.38 (0.37 - 4.37)	5.12E-01
Cholesterol, mmol/L	5.01 (3.20 - 7.40)	5.32 (4.05 - 7.37)	<u>1.51E-03</u>
HDL-C, mmol/L	1.03 (0.67 - 9.40)	1.34 (0.80 - 2.31)	<u>6.64E-10</u>
LDL-C, mmol/L	3.20 (1.60 - 5.51)	3.27 (2.19 - 5.25)	1.07E-01
WBC, × 10 ⁹ /L	10.85 (4.40 - 25.90)	5.50 (2.60 - 9.0)	<u>1.46E-20</u>
Platelet, × 10 ⁹ /L	250.5 (134 - 649)	258 (165 - 599)	3.79E-01
Creatinine, mmol/L	88.5 (51 - 142)	69 (42 - 97)	<u>3.90E-13</u>

hsTnT, pg/mL	1726 (62 - 9819)	6 (3 - 18)	<u>8.83E-28</u>
NTproBNP, pg/mL	718 (68 - 6819)	36 (7 - 150)	<u>3.01E-27</u>

^a Significant *p*-values are underlined.

Abbreviations used in the table: FH, family history; DBP, diastolic blood pressure; SBP, systolic blood pressure; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; WBC, white blood cells; hsTnT, high-sensitivity troponin T; NTproBNP, N-terminal-pro hormone brain natriuretic peptides.

^a Variables presented here are the significant variables ($\alpha = 0.01$) after backwards elimination of model fitted with age, gender, smoking status, race, dyslipidemia, triglyceride, cholesterol, HDL-C, LDL-C, white blood cell, platelet, and creatinine as independent variables.

^b Difference in mean levels of the respective element or element ratio/product associated with a 1-unit increase in the independent variable. Units for each variable can be found in Table 1.

^c Level of significance: *, $p \leq 0.05$; **, $p \leq 0.01$; ***, $p \leq 0.001$; ****, $p \leq 0.0001$.

Table 3. Descriptive statistics and statistical comparisons between metallomic profiles of AMI patients at T1 versus healthy controls.

^a T1, 24-48 hours post-PCI; T2, follow-up at 1 month after T1; T3: follow-up at 6 months after T1.

^b Levels of significance and p-values were derived from the Friedman test. -, $p \geq 0.05$; *, $p \leq 0.05$; **, $p \leq 0.01$; ***, $p \leq 0.001$; ****, $p \leq 0.0001$.

^c Kendall's coefficient of concordance (W) was used as a measure of the Friedman test's effect size. Kendall's W uses the Cohen's interpretation guidelines of: $W < 0.3$, small effect; $W < 0.5$, moderate effect; $W \geq 0.5$, large effect. Confidence intervals are calculated by bootstrap.

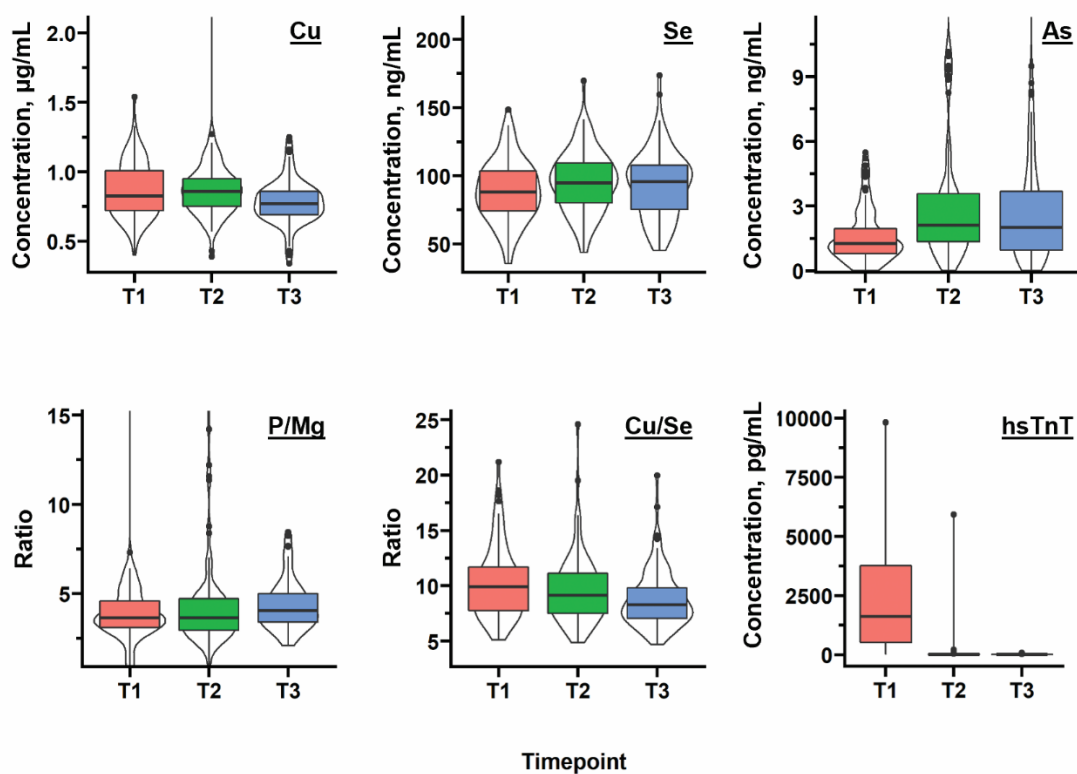

^d Post-hoc pairwise comparisons were done using paired Wilcoxon signed-rank test with Bonferroni adjustment. Level of significance given on the left is derived from comparison between T1 and T2, while the one on the right is from T2 and T3's comparison.
