Sensitivity analysis of the continuous association of fibrotic interstitial lung abnormalities (ILA) as defined by Fleishner Society position paper with SOFA score, lactate dehydrogenase, days of mechanical ventilation, and age-adjusted leukocyte telomere length (LTL) percentile using generalized additive models with LOESS smothers.**

## **Supplemental Methods.**

### *Study Design*

We conducted a single-center prospective cohort study of adults age 21 years and older hospitalized between March 1, 2020 and May 15, 2020 with a positive SARS-CoV-2 RT-PCR nasopharyngeal swab and who required supplemental oxygen. The Columbia University Irving Medical Center (CUIMC) Institutional Review Board study protocol number is AAAR1916. Participants signed a written informed consent.

### *Recruitment and Enrollment*

We enrolled participants by calling via telephone consecutive patients meeting eligibility criteria based on their admission date, with sampling weighted to include approximately 50% survivors of mechanical ventilation. We sought to enroll 70-100 participants based upon the capacity of the research team to recruit and assess participants during the 4-month follow-up study period of July and August 2020. Participants ambulated independently prior to hospitalization, did not live in a skilled-care facility prior to hospitalization, required supplemental oxygen therapy during their hospital stay, and were discharged to acute rehabilitation, subacute rehabilitation, or home. All participants were living at home prior to enrollment. We excluded those with pre-existing interstitial lung disease and those who had undergone lung transplantation.

### *Electronic Medical Record Measurements*

We obtained clinical data from the New York Presbyterian-CUIMC clinical data warehouse, which contains electronic data for inpatient and outpatient visits<sup>1</sup>. Patient data included demographics, diagnoses, procedures, medications, laboratory tests, vital signs and ventilator flowsheet data, and other clinical variables. Past medical history diagnoses were retrieved from the hospital admission notes and by using groups of ICD-10 diagnosis codes

according to the Clinical Classifications Software by the Healthcare Cost and Utilization Project<sup>2</sup>. We calculated the Sequential Organ Failure Assessment (SOFA) score during the first 24 hour of admission<sup>3</sup>.

### *Chest Computed Tomography*

Non-contrast high resolution chest CT scans (HRCT) were performed at maximal inspiration using either GE VCT 64 or GE Revolution CT750 HD instrument. Two chest radiologists (MS and BD) evaluated the scans for radiographic abnormalities, using interstitial lung abnormality (ILA) categories recommended by a recent Fleischner position paper<sup>4</sup> (ground glass opacities, non-emphysematous cysts, reticulations, honeycombing, and traction bronchiectasis) in addition to centrilobular nodules and intra-parenchymal opacities, which have been described in COVID-19 patients<sup>5,6</sup>. The radiographic abnormalities were scored using a semi-quantitative scoring system used by ARDSnet investigators<sup>7</sup>. Those with traction bronchiectasis, honeycombing, or reticulations were categorized as having a fibrotic ILA. All others were categorized as having a non-fibrotic ILA. Radiographic abnormalities were assessed at 5 levels: the aortic arch, 1cm above the diaphragm, and three levels equally spaced between the aortic arch and diaphragm. Each level was divided into four lung quadrants, and scored within each quadrant as: 0=no involvement; 1= <5% involvement; 2= 5–25% involvement; 3=26–49% involvement; 4=50–75% involvement; and 5=greater than 75% involvement. The sum of the quadrant scores at each level was averaged across the five levels to determine the final score (range 0-20). For traction bronchiectasis, an airway abnormality that is difficult to quantify, each level was scored as either 0 or 1 for its absence or presence, respectively, for a maximum score of 5.

In addition to the radiologists' subjective scoring of ILAs, the University of Iowa imaging lab (Iowa City, IA, USA) used the adaptive multiple features method (AMFM) to quantify HRCT

scans for various lung features, including: ground glass opacity, ground glass-reticular, honeycombing, emphysema, or normal lung<sup>8</sup>.

### *Clinical Measurements*

Pulmonary function tests were performed on one of two pulmonary function machines (NDD EasyOne Pro, Andover MA; Vyair Medical VMAX Encore, Mettawa IL). Pulmonary function testing and six-minute walk distance (6MWD) were assessed according to established guidelines<sup>9,10</sup>. Cough was assessed using a 100mm visual analogue scale<sup>11</sup>. Dyspnea was assessed using the UCSD shortness of breath questionnaire<sup>12</sup>.

### *Frailty Measurements*

We measured the five Fried Frailty domains: gait-speed, grip-strength, weight loss, low activity, and exhaustion. We measured grip-strength, gait-speed, and exhaustion, and using the traditional Cardiovascular Health Study (CHS) methodology<sup>13</sup>. Weight loss was calculated as the difference between their hospitalization admission weight and the measured weight during the follow up visit. A decrease >10 lbs. met the Fried Frailty domain requirement. We assessed the physical activity domain on the basis of report of activities performed at four-month follow-up using the Duke Activity Status Index (DASI)<sup>14</sup> instead of the the Minnesota Leisure Time Physical Activity Questionnaire<sup>15</sup>, the original CHS measure of physical activity, as it improves the construct and predictive validity of frailty assessments in ARF survivors<sup>16</sup>. We used previously validated DASI score cutoffs for low activity in older ARF survivors (men  $\leq 12.5$ ; women  $\leq 10$ )<sup>16</sup>.

Each frailty domain is assigned 1 point if present and 0 points if absent based on the established cutoffs (range, 0-5). Consistent with CHS methodology, we defined the frailty phenotype as being frail in  $\geq 3$  of the five domains.

### *Genetic and Genomic Measurements*

Blood was collected from each participant at the follow-up visit. DNA was isolated from blood leukocytes using the Gentra Puregene Blood kit (Qiagen, Valencia CA). Leukocyte telomere length (LTL) was measured using a quantitative PCR assay and the RotoGene real-time PCR system (Qiagen)<sup>17</sup>. The LTL was expressed as a logarithm-transformed ratio of telomere to single-copy gene [ $\ln(T/S)$ ] and this value was compared to LTL from normal control subjects (n=201 unrelated multiethnic individuals from Dallas, TX, ranging in age from 19 to 89 years) to estimate an age-adjusted LTL percentile.

### *Missing Data*

The Glasgow Coma Score, a component of the SOFA score, was missing for nearly all non-ICU patients, and we thus imputed a score of 15 for these participants based on previous literature<sup>18</sup>. Inflammatory markers ESR, CRP, LDH, Ferritin and D-dimer, had 6-12% missingness in a pattern that was not completely random. We used the MICE function in R(v3.5.1) to perform multiple imputation using predictive mean matching for missing values. There were six participants that could not perform the 6-minute walk test because they were non-ambulatory and one whose baseline heart rate was too high to safely perform the test. For the six participants who were non-ambulatory, we imputed 0 and ran a complete case analysis excluding the last participant. Three participants were unable to produce acceptable or reproducible DLCO measure. Given low degree of missingness, we ran a complete case analyses using only participants with complete PFT data.

### *Statistical Analyses*

We examined unadjusted associations of clinical and biomarker characteristics with no ILA, non-fibrotic ILA, or fibrotic ILA using analysis of variance (ANOVA), Kruskal Wallis, or chi-squared tests. We calculated correlation coefficients between continuous data using

Spearman's method. We examined adjusted associations of fibrotic ILA with the hypothesized and biologically plausible independent variables that were associated with fibrotic ILA in unadjusted analyses. Due to the moderate cohort size and rate of fibrotic ILA, we used generalized covariate balanced propensity scores (CBPS) to adjust for potential confounders so as to avoid model overparameterization, as has been done in prior studies<sup>19</sup>. We generated propensity scores predicting each of the independent variables of interest using the CBPS function in R(v3.5.1)<sup>20</sup>. To do so, we calculate CBPS for each independent variable by regressing it on a set of potential confounders age, sex, race/ethnicity, days since infection, body mass index, pack-years of smoking, treatment with steroids while hospitalized, and the two other independent variables of interest. We created separate generalized additive logistic models (GAMs) for each independent continuous variable. The resulting CBPS was then included in the GAM model as an additional covariate. In the GAMs, we did not assume linear associations between continuous independent variables and risk of fibrotic ILA, and instead estimated associations by a nonparametric locally weighted smoothing spline. For lab values like LDH, we removed outliers beyond 2 standard deviations for the analysis. For independent variables without evidence of non-linear associations with fibrotic ILA in the GAMs, we estimated adjusted odds ratios using logistic regression models. Since LTL may increase severity of illness<sup>21</sup>, and since LTL may be affected by critical illness<sup>22</sup>, we conducted sensitivity analyses: one estimating associations of LTL, admission SOFA score, LDH, and duration of mechanical ventilation with fibrotic ILA without adjusting for the other three independent variables. The second sensitivity analysis was performed with a more conservative definition of fibrotic ILA that comprises only traction bronchiectasis and honeycombing<sup>4</sup>. Covariates were found to be balanced in all propensity scores (see **Table S5**)<sup>23,24</sup>. Analysis were performed using Stata/IC v16 (StataCorp) and R, v3.5.1.

**Table S1. Demographic and clinical features of COVID-19 survivors.**
